# PAPERS AND PROCEEDINGS

## (In May 1964 Number)

### AMERICAN ECONOMIC HISTORY, REAPPRAISALS IN

A New Look at Hunter's Hypothesis about the Antebellum Iron Industry.....	P. TEMIN.....	344
Antebellum Interregional Trade Reconsidered.....	A. FISHLOW.....	352
Canals and Development: A Discussion of the Issues	R. L. RANSOM.....	365
<i>Discussion</i> by R. W. FOGEL.....		377

### CANADIAN-AMERICAN ECONOMIC RELATIONS: EFFICIENCY AND INDEPENDENCE

The Canadian Tariff and The Efficiency of the Canadian Economy.....	H. C. EASTMAN.....	437
The Exports of American-owned Enterprises in Canada.....	A. E. SAFARIAN.....	449
The U.S. Tariff and The Efficiency of the U.S. Economy.....	R. M. STERN.....	459
<i>Discussion</i> by L. B. KRAUSE, C. P. KINDLEBERGER, J. H. YOUNG.....		471

### COMPARATIVE COSTS AND ECONOMIC DEVELOPMENT

Comparative Costs and Economic Development: The Experience of India.....	W. MALENBAUM.....	390
Comparative Costs and Economic Development: The African Case.....	W. A. CHUDSON.....	400
Import Substitution and Industrialization in Brazil.....	W. BAER AND L. KERSTENETZKY.....	411
<i>Discussion</i> by A. O. HIRSCHMAN, W. F. STOLPER, R. VERNON.....		426

### EFFICIENCY IN AGRICULTURE

Efficiency of the Farm Firm.....	E. O. HEADY.....	97
Factor Market Efficiency for Agriculture.....	G. S. TOLLEY AND B. M. FARMER.....	107
<i>Discussion</i> by K. L. ROBINSON.....		120

### EFFICIENCY IN THE GOVERNMENT SECTOR

Fiscal Institutions and Efficiency in Collective Outlay.....	J. M. BUCHANAN.....	227
The Structure of Government and Public Investment	JULIUS MARGOLIS.....	236
Divergences between Individual and Total Costs within Government.....	R. N. MCKEAN.....	243
<i>Discussion</i> by M. OLSON, JR., N. ROSENBERG, J. ROTHENBURG.....		250

### EFFICIENCY IN THE LABOR MARKETS

Relative Employment Effects of Unionism.....	H. G. LEWIS.....	123
Labor Mobility and Wage Inflexibility.....	R. L. RAIMON.....	133
The Featherbedding Problem.....	P. A. WEINSTEIN.....	145
<i>Discussion</i> by W. G. BOWN AND G. H. HILDEBRAND.....		153

## EFFICIENCY OF THE SOVIET ECONOMY

The Static Efficiency of the Soviet Economy.....	J. S. BERLINER.....	480
The Dynamic Efficiency of the Soviet Economy.....	B. BALASSA.....	490
International Division of Labor in CEMA; Limited Regret Strategy.....	E. NEUBERGER.....	506
Discussion by J. THORNTON, E. D. DOMAR, F. L. PRYOR.....		516

## EFFICIENCY IN THE TEACHING OF ECONOMICS: THE PRODUCT

The Problem of Communication.....	L. S. SILK.....	595
Economic Analysis and Public Policy: The Growing Hiatus.....	R. R. NATHAN.....	610
Discussion by J. A. KERSHAW, K. A. KNOPF, H. H. VILLARD.....		623

## EFFICIENCY IN THE USE OF NATURAL RESOURCES

Attainment of Efficiency in Satisfying Demands for Water Resources.....	I. K. FOX AND O. C. HERFINDAHL.....	198
The Marine Fisheries: A Problem in International Cooperation.....	J. CRUTCHFIELD.....	207
Efficiency of Resource Use in Crude Petroleum: Abstract.....	M. A. ADELMAN.....	219
Discussion by A. E. KAHN, D. J. WHITE, N. WOLLMAN.....		221

## EFFICIENCY, PRINCIPLES OF

The Measurement of Waste.....	A. C. HARBERGER.....	58
Efficient Allocation of Capital in an Uncertain World.....	J. HIRSHLEIFER.....	77
Discussion by D. W. JORGENSON, W. VICKREY, T. C. KOOPMANS, P. A. SAMUELSON.....		86

## ELY, RICHARD T., LECTURE

Economic Growth as an Objective of Government Policy.....	J. TOBIN.....	1
Discussion by H. G. JOHNSON, H. STEIN.....		21

## FINANCIAL FACTORS IN BUSINESS CYCLES

Financial Markets in Business Cycles: A Simulation Study.....	F. DE LEEUW.....	309
Longer Waves in Financial Relations: Financial Factors in the More Severe Depressions.....	H. P. MINSKY.....	324
Discussion by J. DUESENBERY, J. G. GURLEY, A. H. MELTZER.....		336

## INVITED DISSERTATIONS, I

The Monetary Mechanism: Some Partial Relation- ships.....	J. L. PIERCE.....	523
The Term Structure of Interest Rates.....	B. G. MALKIEL.....	532
Commercial Bank Portfolio Adjustments.....	W. R. RUSSELL.....	544
Discussion by M. J. BAILEY, A. OKUN, R. E. QUANDT.....		554

## INVITED DISSERTATIONS, II

The Determinants of Volume in a Probabilistic Market.....	F. T. SPARROW.....	559
The Federal Rivers and Harbors Program: An Analysis of Regional Impact.....	R. HAVEMAN.....	568

Farmer Response to Price in a Subsistence Economy:	
The Case of West Pakistan.....	W. P. FALCON..... 580
<i>Discussion</i> by C. C. HOLT, D. G. JOHNSON.....	592
MONOPOLISTIC COMPETITION AFTER THIRTY YEARS, THEORY OF	
The Impact on Industrial Organization.....	J. S. BAIN..... 28
The Impact on General Theory.....	R. L. BISHOP..... 33
Monopolistic Competition and Welfare Economics.....	W. J. BAUMOL..... 44
<i>Discussion</i> by J. W. MARKHAM, P. O. STEINER.....	53
THE REGULATED INDUSTRIES	
The Effect of Rate Regulation on Resource Allocation	
in Transportation.....	G. Wilson..... 160
Direct Regulation and Market Performance in the	
American Economy.....	R. E. CAVES..... 172
The Effectiveness of Economic Regulation: A Legal	
View.....	R. C. CRAMTON..... 182
<i>Discussion</i> by E. W. WILLIAMS, JR., R. H. COASE.....	192
TAXATION, PROBLEMS IN	
Direct Shifting of the Corporation Income Tax in	
Manufacturing.....	C. A. HALL, JR..... 258
The Tax Structure and Corporate Dividend Policy.....	J. A. BRITTAIN..... 272
Economic Effects of the Capital Gains Tax.....	M. DAVID..... 288
<i>Discussion</i> by R. A. MUSGRAVE, J. LINTNER, E. C. BROWN.....	300

## CONTRIBUTORS:

Leading articles are marked (a); communications (c); papers read at the annual meeting, published in the Papers and Proceedings, separately paged, are marked (p); review articles (r); and all others are book reviews.

## INTEGRATION AND GROWTH OF THE WORLD ECONOMY IN HISTORICAL PERSPECTIVE\*

*By* GOTTFRIED HABERLER

We live in the age of integration. Every conceivable—or inconceivable—combination of countries has been proposed, more or less seriously, as a candidate for integration—other planets and outer space being almost the only areas that do not yet figure in any of the many plans and proposals. With the formation of the European Economic Community, the European Common Market as a going concern, integration has passed from the talking stage, where it had remained for many years, into the stage of concrete realization. The example of the Common Market, beside spawning a rival European combination (EFTA), has induced the creation of similar schemes in other parts of the world—in South and Central America—and still others are on the drawing board. I do not intend to offer yet another comparative analysis of any of those schemes. What I should like to do is to put the modern integration movement into broader historical perspective of the growing world economy.

Without wishing to engage in a lengthy discussion of the proper or useful definition of terms, I think I should first indicate very briefly what we mean by integration—I say “we” and not “I,” because I hope for fairly general agreement. We mean by integration closer economic relations between the areas concerned. This is clearly a concept capable of continuous gradation. One first stage is characterized by free commodity trade, greater division of labor, tending toward equalization of commodity prices. We have a higher stage of integration when factors of production can move freely with a consequent tendency for factor price equalization. (Allow me to skip the famous controversy whether complete factor price equalization would result from free commodity trade alone, with the remark that such equalization could indeed result, but only under such unrealistic assumptions that for practical purposes we can say that it would *not*. I hope that speaking

\* Presidential address delivered at the Seventy-Sixth Annual Meeting of the American Economic Association, Boston, December 27, 1963.

of "unrealistic assumptions" will not embroil me in another famous and as yet unresolved controversy—namely, whether it is possible to reach reasonable conclusions from absurd premises.) We have a still higher stage of integration if all or the most important phases of economic policy are coordinated, and positive steps are taken to equalize commodity and factor prices.

I shall refrain from arbitrarily designating, as some have done, any one stage as that of "true integration" and shall not go into the substantive question whether the achievement of a lower stage of integration by itself may have undesirable results which would involve probing the mysterious depth of the theory of the "second best."

### I. *Waves of Integration*

The recent movements toward integration are often regarded as an entirely new development which has been envisioned and proposed by many but has never before made headway on a significant scale. I submit that this is true only in a formal and narrow sense.

Looking over the evolution of the world economy during the last two hundred years or so, we can clearly discern three big waves of integration—preceding and dwarfing the regional integration movements of the last ten years. The secular trend toward integration and growth of the world economy was interrupted by one period of sharp decline and disintegration.

Let me first briefly identify these partly overlapping waves and then discuss them in turn.

The first wave was the internal integration of the economies of the nation states which we find today on the map of the world. The economy of Great Britain was the first to be unified and integrated, the French and American followed soon after. Later came other Continental European and overseas countries.

The second wave overlapping or, if you prefer, superimposed upon the first was the free trade movement that reached its high point at the end of the 1870's. The movement towards freer trade was reversed in 1878, but despite the fact that in most countries tariffs became higher and higher, world trade continued to grow rapidly up to World War I. For the underlying forces of rapid technological progress in transport and mass production, as well as massive migration of labor and capital toward the regions of "recent settlement" in the Western Hemisphere, Oceania, and South Africa, still dominated over increasingly protectionist commercial policies in many parts of the world. The more drastic modern methods of trade restriction, quotas and exchange control, had not yet made their appearance, and the movement toward collectivism, interventionism, and national economic planning, which

later became a formidable obstacle for world-wide integration, had not yet made much headway.

The first serious disintegration of the world economy, foreshadowed by the rising protectionism and economic nationalism from 1880 on, became a fact during and immediately after the World War of 1914-18. After a brief interlude of freer trade in the 1920's, real disintegration and rapid decline of world trade set in with the Great Depression. After an incomplete and hesitant recovery, disintegration reached its nadir in World War II.

The third wave of world-wide integration and growth started soon after the end of World War II, gathered momentum after 1948, and is still in progress. It has been centered on and propelled by the spectacular recovery and rapid growth of all industrial countries, including the United States and United Kingdom, notwithstanding their recent troubles and their lower growth rates compared with the Continent of Europe and Japan. Contrary to what is often said, the prosperity of the "industrial centers" of the world economy did spread, though not as rapidly and fully as one would wish, to the "periphery" of the less developed countries, to use Raul Prebisch's picturesque designation of the two areas. This wave of world-wide integration has had more powerful and beneficial effects than the much more advertised and talked-about series of regional integrations.

## II. *National Economic Integration*

Let me now add some observations on each of these phases of the growing world economy. Later I shall analyze recent developments in somewhat greater detail in the light of the historical perspective gained.

The internal integration of the British and French economies was vigorously pursued during the mercantilistic era. The economy of Great Britain emerged as a fully integrated unit in the eighteenth century and the economic integration of France was completed when the French Revolution swept away all still existing internal barriers to trade and migration. In both countries, as well as in almost all others, political and administrative unification and centralization preceded and promoted economic integration. Early attempts at close Anglo-French economic co-operation, sponsored by the physiocratic advisers of Louis XVI and by Adam Smith's influence on the younger Pitt, culminated in the Eden Treaty of 1786 which brought drastic tariff reductions. But the movement toward freer trade was premature and was soon interrupted by the French Revolution and the following wars. Not before 1860 was the time ripe to accomplish what had been tried 75 years earlier.

The American economy had the good fortune of having been integrated at a very early stage. When the War of Independence came to an end, the economic relations between the states resembled those of the German states after the Congress of Vienna. Under the Articles of Confederation each of the 13 states of the Union pursued its own tariff policy. But through the Constitution a huge free trade area for the unimpeded movement of goods and services, of labor and capital was created, which was surely a major factor in U.S. economic development.

On the Continent of Europe the major steps toward integrated national economies were the economic unification of Germany through the German *Zollverein* (1834) and the emergence of a unified Italian state in 1861.

Alfred Marshall called the *Zollverein* "the most important movement toward free trade that the world had ever seen, except the contemporary reform of the British fiscal system" [12, p. 399]. I think Marshall was right, for from the political and historical standpoint, if not from the economic one, national economic unification was an indispensable prerequisite not only for the economic development of the various countries concerned, but also for the growth of the world economy. This remains true even though we now know that the hopes and expectations so widely held in the mid-nineteenth century, that national free trade and integration would lead in straight and unbroken succession to world-wide free or near-free trade, were not fulfilled. To question Marshall's judgment concerning the *Zollverein* on the ground of the next hundred years of German history would imply extreme and untenable historical determinism.

There is no doubt that the Italian unification did for the development of the Italian economy as a whole what the German unification did for the German economy. This would be true even if the widely held theory were correct that the economic integration and internal free trade caused a retardation of the economic development of the Italian South as a region in an absolute sense, not merely relatively to the more progressive North.

The German and Italian national economic integration was preceded and followed by similar movements in many other European and overseas countries.

### III. *World-Wide Integration Through Freer Trade*

While this was going on, the second wave of world-wide integration, as I called it, started—namely, the free trade movement of the mid-nineteenth century. It was spearheaded by Great Britain, but spread widely (especially after 1860) to the Continent of Europe. Let me briefly recall a few landmarks—abolition of the Corn Laws in 1846,

the Cobden-Chevalier Treaty of 1860 between Great Britain and France, which brought a radical reversal from high protection to something near free trade in France, and following the Franco-British accord a number of commercial treaties which substantially reduced tariffs all over Western and Central Europe. The impact of the free trade movement was not confined to commercial policy and tariffs. Shipping policy, which was extremely restrictive everywhere in the early nineteenth century, was radically liberalized, first in Great Britain as early as the 1830's and later in other countries. Furthermore, the introduction of the "open door" policy in the British crown colonies and in others was a major step towards the liberalization of world trade.

As far as tariff policy is concerned, the movement towards freer trade came to an end in the last years of the 1870's. The two major factors that caused the reversal of liberal commercial policy, first in Germany (1878) and a little later in France and elsewhere, were the accelerated influx of agricultural products from overseas countries—United States, Canada, Argentina, Australia—and the impact of the severe depressions of the 1870's and 1890's. But although import tariffs in many countries showed a definite tendency to go higher during the last quarter of the nineteenth century and the first decade of the twentieth century, the volume of world trade rose rapidly throughout the whole period up to World War I. From about 1895 the rate of growth was indeed substantially higher than during the preceding two, and possibly three, decades.

A number of factors account for the growth of trade in the face of rising tariffs. The technological revolution in production and transportation continued, of course, without let-up. However this factor alone might not have been sufficient to support the growth of world trade as is shown by the development during the next period, namely the interwar years during which world trade did not show much growth, although one could hardly say that technological progress had slowed down.

The flow of capital and especially of labor from Europe to the Western Hemisphere and a few other areas continued at a rapid and increasing rate until 1914, after which it slowed down sharply. Moreover, while tariffs went higher after 1878, they were on the whole still moderate compared with those prevailing after World War I and, what is equally important, much more stable. Furthermore, the international payments mechanism improved with the adoption of the gold standard by many countries in the last quarter of the nineteenth century. International clearing of balances aided by the easy flow of short-term credit through London and other financial centers in Western Europe and elsewhere promoted multilateral trade around the globe. Payment restric-

tions were, of course, almost totally absent, and so were other quantitative trade restrictions such as quotas and export or import monopolies.

We are thus justified, it seems to me, to speak of a long period of world-wide integration during which most countries were knit together ever more closely in a network of multilateral trade and payments. It is true that many writers—most of them later with the benefit of hindsight, though one can also find a few contemporary prophets of doom—thought that they could detect tendencies of incipient disequilibrium and disintegration. As far as the economics of the matter is concerned, these are merely *ex post* rationalizations and explanations of what happened later. It is only in the field of ideologies, it seems to me, that a case can be made for the theory that later events were the likely and natural (though not the unavoidable) consequence of earlier tendencies. Concretely, it can perhaps be argued that the rising tide of economic and political nationalism and antiliberal thinking and policies in general led to World War I and its aftermath. But there surely was no inevitable economic nexus in the sense that a deep-seated real maladjustment had arisen in the world economy, something analogous to what is supposed by many business cycle theorists to develop in major if not all business cycle upswings—a real disequilibrium which makes a painful and long drawn out readjustment all but inevitable.

The statement that there was nothing basically wrong with the pre-1914 world economy will probably not encounter strenuous objections from the present generation of economists, although it is contradictory to Marxian-type theories, especially the neo-Marxian theory of imperialism, and to the Keynesian secular stagnation doctrine.

But the justification of what I have said must to a large extent rest on the plausibility of an alternative explanation of the events of the next thirty years.

#### IV. *Disintegration of the World Economy, 1914-45*

The period from 1914 to 1945, bordered by two world wars and bisected by a catastrophic depression, can surely be described as one of disintegration of the world economy and declining world trade, under any reasonable definition of these terms.

The disintegrating forces were so strong that it is surprising that world trade did expand at all. Let me briefly recall the major developments.

World War I was followed by acute financial disorders, rapid inflation in many countries and hyperinflations in some. In the United States, the period of inflation ended in the severe depression of 1920-21 which had repercussions in many countries around the world, while in

Europe inflation was stopped abruptly in a series of successful stabilization efforts between 1922 and 1925 without any immediate depressive effects.

By the middle of the 1920's the world was back on what looked like a normal course with most currencies again convertible. It is true, tariffs were higher and less stable than before and had a tendency to go higher; moreover, the integrated area of the Austro-Hungarian monarchy was fragmented into several pieces. But despite these unfavorable developments, world trade expanded fairly rapidly to something like 30 per cent above the prewar level. The effective exclusion of Russia from the world economy, although an event of tremendous political consequence, had a very limited economic impact on the world economy during the interwar period.<sup>1</sup>

Then came the Great Depression and the picture changed completely. The few remaining free trade countries, Great Britain<sup>1a</sup> first, switched abruptly to high protection. Tariffs everywhere were raised rapidly and almost all countries introduced quotas, exchange control, import prohibitions, bilateral clearings—methods of international trading which in peacetime had literally not been known for centuries. By 1932 the dollar value of world exports had tumbled to about a third of its 1929 level and its quantum was where it had been in 1913.

The quantum of trade in manufactured articles declined much faster than that of trade in primary products, but the value of the latter fell more, which reflects the extremely sharp deterioration of the terms of trade for the exporters of primary products.

In 1938 the quantum of trade of primary products was again 16 per cent above the 1913 level. While the world index of manufacturing activity in 1936-38 was 85 per cent above the 1913 level, the quantum of trade of manufactured articles was some 8 per cent below 1913 [3] [25, Ch. 2.]<sup>2</sup> This contrast can be regarded as a rough indication of the degree of disintegration of the world economy that had taken place.

For the purposes of this paper, as indicated above, I have to venture to express my views on the basic causes of the exceptional severity and length of the Great Depression. At the time when it happened most

<sup>1</sup> It is interesting that only at the lowest point of the depression in 1931-32 did trade with Russia temporarily assume a somewhat greater importance for some European countries.

<sup>1a</sup> It is true that during and immediately after World War I Great Britain applied a stiff dose of tariff protection (the so-called "MacKenna" and "Key Industry" duties). But they applied only to a short list of industrial articles, and some were temporarily removed by Philip Snowden, Chancellor of the Exchequer in the first MacDonald ministry in 1924.

<sup>2</sup> The concept "world manufacturing activity" is, of course, somewhat nebulous and its measure arbitrary and imprecise. But the statements in the text could be restated in terms of GNP, industrial production, and trade of the major countries, concepts that are less objectionable than "world production," etc.

economists did not know what had hit them. Marxian economists, of course, took the economic catastrophe simply as a confirmation of Marx's theory that depressions would become more and more severe until the capitalist system would come down in a final big crash. (In the 1960's this view has lost conviction, even among the faithful.) Others who lacked the prophet's guidance through the maze of world history had a harder time to explain the slump. Some spoke vaguely of big real maladjustments in the structure of production that had accumulated during the 1920's and others of the coincidence, accidental or otherwise, of the contraction phase of several superimposed types of concurrent economic fluctuations.<sup>3</sup> The Keynesians later fashioned their theory of secular stagnation.

From the present vantage point, the explanation of the exceptional virulence of the Great Depression seems much simpler. It was mainly due to the wholesale destruction of money, which in turn was largely the consequence of institutional weaknesses and incredibly poor policies, on the national and international level. Let me mention only a few of these. The collapse of the American banking system, the bankruptcy of thousands of banks, and the overly timid<sup>3a</sup> monetary policy which failed to counteract energetically and to stop the raging deflation explain, I venture to say, the "darkest hues" (Schumpeter) of the depression in the United States. Money supply contracted by something like 30 per cent from 1929 to 1933. The deflation could not have been nearly as severe if there had existed then, as there exists now, effective deposit insurance, or if the United States, instead of the archaic unit banking system, had had an efficient branch banking system like Great Britain,<sup>4</sup> not to mention "100 per cent banking."

The mistakes of the early New Deal of pressing hastily for often poorly conceived reforms, of fostering monopolies of business (N.R.A.) and labor and thus raising costs and frightening investors, instead of concentrating at first all energies on expansionary measures to bring about quick recovery (as Keynes among others recommended), explain why in 1939 unemployment was still over 17 per cent. Policy mistakes of a similar kind and magnitude were made in several other important countries, for example in pre-Nazi Germany and under the popular front government in France. Just as Roosevelt ignored Keynes' sug-

<sup>3</sup> Schumpeter himself did not really take seriously his suggestion that the coincidence of a Kondratieff, Juglar and Kitchin depression accounted for the severity of the 1930 depression. On the contrary, he said that "the darkest hues of cyclical depressions . . . are due to adventitious circumstances." See [19, p. 150].

<sup>3a</sup> The timidity of monetary policy should be judged by the magnitude of the problem (the intensity of the deflation which was to be offset) and not by historical standards.

<sup>4</sup> If anybody doubts this statement, let him read Jacob Viner's brilliant, convincing, and blunt but well-balanced analysis in [24]. Also see [1].

gestion that he postpone reforms until recovery had made good progress, so did Léon Blum the advice of his Scandinavian and British socialist friends who recommended that expansion take precedence over reform.<sup>5</sup>

On the international level the slow-motion, beggar-my-neighbor devaluation of all currencies of the world at intervals of a few years—sterling in 1931, the dollar in 1933-34, the gold bloc currencies in 1936 and so on—inflicted upon different groups of countries protracted periods of overvalued currencies, causing deficits and losses, further trade restrictions, and more depression. Although each of these devaluations in isolation can be defended as unavoidable, their time pattern stamped the whole approach as a sadistic policy, calculated to maximize pain and destruction. It was like cutting off the tail of a dog piece by piece instead of all at once, the way it surely would have been done had there existed the *International Monetary Fund*.

These institutional defects and horrendous policy mistakes have nothing to do with basic weaknesses or contradictions of the capitalist, free enterprise economy, or with a tendency toward secular stagnation, lack of investment opportunities and a chronic tendency toward over-saving, or gigantic real maladjustments. At any rate, wherever the monetary deflation was stopped by orthodox or unorthodox measures without at the same time sharply raising costs, the alleged real, structural contradictions, weaknesses, and maladjustments disappeared as fast as they had appeared a few years earlier.

It is true the methods used to stop deflation were very unorthodox in many countries (not in all), and there remained almost everywhere a legacy of high tariffs, tight quotas and many other restrictions on international trade and payments. But the point is that this was not necessary; deflation could have been stopped and the economy "re-flated"<sup>6</sup> in a more orderly, less unorthodox fashion with less structural change and without damage to the international division of labor. Even as it was, if in the meantime the threat of war had not arisen and the war had not come, surely a good part of the new trade barriers would have been removed and trading methods would have returned to a more normal state of affairs. Actually, the outbreak of World War II delayed the return to something resembling the pre-1929 conditions until the 1950's.

<sup>5</sup> On Keynes' criticism of the New Deal policies compare R. F. Harrod, *The Life of John Maynard Keynes*, New York, 1951, p. 447. Keynes was critical not of the reforms as such, but of the timing of their introduction and of the methods of putting them through, which, by frightening the businessman, unnecessarily delayed full recovery.

The information concerning Léon Blum I owe to Gunnar Myrdal.

<sup>6</sup> This does not mean that the price level would have to go back to the 1929 level.

Before going on to those recent developments, let us look back once more at the interwar period. As it recedes into the past and we gain perspective, it becomes increasingly clear, it seems to me, that the interwar or two-war period in general and the Great Depression in particular were in many important respects a singular historical phenomenon.

Let me become more concrete. I have already mentioned that the exceptional severity and length of the Great Depression were due to special circumstances, institutional weaknesses, and incredibly inept and timid policies on the national and international level. This has been misunderstood by the Marxians and Keynesians. The doctrine of secular stagnation, the widely held expectation that World War II would soon be followed by a deep depression—an expectation which was still entertained by many when the second and even when the third postwar recession came around—all these misjudgments as well as the theory of the stubborn dollar shortage and the low elasticity of international demand stem largely, if not wholly, from the misinterpretations of the depressed 1930's as a more or less regular business cycle downswing. A period of singular catastrophes plays havoc with trend extrapolations, and many an analysis has come to grief. Examples in the domestic field are the numerous estimates of saving propensities and investment opportunities for the postwar years on the basis of interwar experience and figures. Formidable difficulties arise for another type of analysis—namely that which assumes the existence of some sort of supercycle, be it Kondratieff or the now much more popular Kuznets cycle. It is difficult to see how an endogenous mechanism producing such swings or cycles could fail to be completely disrupted by the elemental forces of a world war or the Great Depression.<sup>7</sup> In the international field, the famous conjecture that the terms of trade have a secular tendency to deteriorate either for the less developed countries or for primary producers is to a large extent the consequence of not recognizing the interwar period with its two very sharp price declines—in 1920-21 and 1929-33—as a singular event. In the light of later developments, this conjecture has lost its statistical support entirely.<sup>8</sup> We shall encounter other cases of analyses that have gone astray for the same reason.

<sup>7</sup> It is possible by means of population or investment echos or some financial mechanism to make a plausible case for the proposition that a tendency for long swings is started by those powerful disturbances. But the attempt to carry the chronology of the long swings right through the disturbed period of 1914-45 and thereby to suggest that the mechanism, whatever it is, which produces the long swings should function more or less undamaged right through that period, punctured though it was by tremendously powerful exogenous shocks, seems to me entirely unconvincing and to compromise the long-swing hypothesis.

<sup>8</sup> The latest extremely careful evaluation is contained in Robert E. Lipsey's important book [11].

### V. *The Growth of World Trade Since the War: The Case of the Industrial Countries*

I now come to the third wave of world-wide integration or reintegration during the postwar period.

Since the end of the war, especially since 1948, world trade has grown very rapidly. World exports rose from some \$54 billion in 1948 to over \$140 billion in mid-1963, and for the decade 1950-60 the compound rate of growth of the volume of world exports was about 6 per cent a year.<sup>9</sup> It seems that for the first time in almost a hundred years world trade has grown faster than world production for a period of more than ten years. I mention this fact for two reasons, first, to convey an idea of the rapidity of the growth and, second, because so much has been made of the alleged fact that since the late nineteenth century international trade has in most countries grown less fast than national income. You will remember that years ago Werner Sombart tried to establish a "historical law" of the "declining importance of international trade."<sup>10</sup> This alleged tendency has held a strange fascination for many economists.<sup>11</sup> But I myself cannot see much importance in this particular criterion. Whether trade has grown somewhat more or less fast than GNP is hardly very significant unless the divergence is very pronounced as it was in the 1930's. Here again the contours of the trend have been blurred by the singular events of the Great Depression.<sup>12</sup>

The rapid rise in world trade is the consequence of, but has also powerfully contributed to, the rapid growth of world production. The performance with respect to growth and stability of the majority of national economies of the world has, on the whole, been satisfactory—not in an absolute sense of perfection, but satisfactory compared first with earlier periods (not only the definitely unsatisfactory interwar period), compared secondly with what was expected by many economists 20 years ago, and compared thirdly, I dare say, with what one

<sup>9</sup> In average of 1955-60 prices. See [4] [22].

<sup>10</sup> "*Die These von der abnehmenden Bedeutung der internationalen Handelsbeziehungen*" or "*der fallenden Exportquote*," Werner Sombart in [20, pp. 368-71].

<sup>11</sup> See [16] for a good, brief discussion and references to the recent literature.

<sup>12</sup> Lipsey [11, p. 44] found that as far as the United States is concerned "over the whole period [1879-1960] the only suggestion of a downward trend in the ratio of the quantity of trade to output was the low interwar export and postwar import ratios. Both now appear to have been temporary." Lipsey reached his results by using constant dollar rather than current value trade figures. The difference between current and deflated dollar value ratios of trade and output stems from the fact that both export and import prices have fallen in the long run compared with domestic prices. Hence a different deflator has to be used for the two items of the ratio. If "invisible" exports and imports could be added to merchandise trade, the statistical support for the theory of the declining trade-GNP ratio would be further weakened.

would gather from current statements of many experts, not to mention politicians, statesmen, and other laymen.

Let me first discuss the case of the highly developed industrial countries. As far as Continental Europe, Japan, and Australia are concerned, my optimistic statement will probably not be questioned. These countries can indeed look back to a decade and a half of almost unprecedented and unbroken growth and prosperity, which has definitely gone beyond the stage that could be reasonably regarded merely as recovery from the low levels reached at the end of the war. But I go on to say that an objective evaluation shows that, contrary to what is often said or implied, the over-all performance of the American economy, too, has been quite satisfactory in the sense defined above. This holds for the whole postwar period including the last five or six years of slightly slower growth and somewhat higher unemployment of which we have heard so much in recent years. True, the U.S. rate of growth has been much lower than that of Europe and Japan, but it has been somewhat higher, over all and per capita, than it was, not only during the whole interwar period, but for any period of similar length (leaving out the Great Depression) since 1909 when reliable deflated GNP figures begin. In the nineteenth century, aggregate GNP grew faster, but as far as we can tell per head or per man-hour growth was slower than during the postwar period.

The great improvement of the postwar years over earlier periods is, of course, the complete absence of deep depressions. This is common knowledge and it is, I think, fairly generally agreed now that there are excellent reasons for assuming that deep depressions are a thing of the past. I share this conviction and shall not repeat the well-known argument. But let us recall that this consensus, which now seems to extend even to Marxist economists, did not exist or was at least much less widespread only ten years ago.

But how about the last five years of somewhat slower growth and higher unemployment? The critics of our economic system call it semi-depression, just about the best one can expect under a capitalist free enterprise regime. Many others agree with the diagnosis of an intolerable stagnation, but think that it could be cured by bold expansionary measures. Some think that monetary and fiscal expansion alone would not be enough, that drastic structural reforms (retraining of workers on a massive scale, redistribution of income, and others) would be required to get the economy back to a high level of employment and to keep it there.<sup>13</sup>

To me any comparison with the 1930's, quantitative or qualitative, seems to be entirely unwarranted, and structural factors explain only

<sup>13</sup> The most extreme position has been taken by Gunnar Myrdal in [14].

a small fraction of the problem. The explanation of the slack is really quite simple: It is the consequence, directly and indirectly via somewhat tighter monetary and fiscal policies than otherwise would be necessary, of the deficit in the balance of payments.<sup>13a</sup>

To put the matter in the simplest terms, suppose the deficit in the balance of payments disappeared all by itself—as it well may through continued inflation abroad—can anyone doubt that our economy would expand substantially, partly from rising exports and import substitution, partly in response to easier money and fiscal policies which then would become possible?

It is really as simple as that although, looking at the size of the deficit compared with GNP itself or with its annual increases, it may sound astonishing that such a tiny tail should wag such a huge dog. But let me get back to my main theme by brushing aside a mountain of real and imaginary difficulties and controversies with the remark that it cannot be beyond the wit of men—that is, us economists—to get this tiny tail removed, with or without the surgery of a change in exchange rates, and without in the process restricting trade in goods and services or reducing growth itself below the otherwise attainable level.<sup>14</sup>

An indispensable condition for the rapid recovery and growth of the industrial countries and the expansion of world trade was the removal of the jungle of internal and external direct controls that had grown up in many countries during the depression and the war. Price controls, consumer rationing, allocation of raw materials, etc. were removed quickly in some countries such as Germany and more gradually elsewhere. By the middle 1950's the process was substantially finished almost everywhere and the price mechanism had again taken the place of the wartime system of direct controls. The liberation of the economies of the industrial countries in Europe and elsewhere from the shackles of direct control released great energies which led to the spectacular rise in output and consumer satisfaction. I add "consumer's satisfaction" because improvements in quality of products and a great

<sup>13a</sup> William McC. Martin, Jr., Chairman of the Board of Governors of the Federal Reserve System, has acknowledged the role of the balance of payments. "I am convinced that our failure to solve the problem [of the balance of payments] up to now has not only been damaging to our international relations but has also impeded the achievement of even high levels of output and resource utilization" (statement before the House Committee on Banking and Currency, July 22, 1963, *Fed. Reserve Bull.*, Aug. 1963, p. 1062).

Since the slack is small, it cannot be far off the mark to say that the external deficit has been the major cause of the slowdown.

<sup>14</sup> I do not wish to say, of course, that in the absence of a balance-of-payments deficit there will never again be a recession or a period of slack. For example, if at a higher level of employment wage-push became stronger and prices started to creep up again, the monetary and financial brakes would sooner or later be applied as they were in the late 1950's with the same general result. But demand inflation, wage-push, Phillips curves, income policy, and all that are not the subject of this talk.

increase in the variety of products (including services such as increased opportunity to travel) surely are factors adding greatly to economic welfare while finding inadequate expression in output figures.

In the international sphere the replacement of direct controls by the price mechanism was much slower and in some countries less complete than in the domestic area. But by 1959 the currencies of all industrial countries were again more or less convertible; in other words, exchange control was dismantled although restrictions on capital movements still exist in many countries. Moreover, import quotas were gradually removed, first in intra-European trade, but then largely also on dollar imports and later, although still incompletely, on imports from Japan.

This freeing of trade constitutes a movement towards world-wide integration that has preceded and overlapped the regional reduction of trade barriers and regional integration in the European Common Market and other similar schemes of which we hear so much. There can be hardly a doubt that, up to now, the quantitative effects on trade of the world-wide integration and liberalization have been much greater than those of the much more discussed and advertised regional schemes.

#### VI. *The Growth of World Trade and the Less Developed Countries*

Now to the controversial and extremely important question of the participation of the less developed countries in the over-all expansion of world trade. From a careful study of postwar facts and figures, the conclusion emerges, I believe, that the less developed countries have greatly benefited from the expansion of world trade and that the prosperity in "the industrial centers" has spread to "the less developed periphery."

This result is not surprising; both classical and Keynesian theory, speaking with complete harmony on this matter, lead to the strong presumption, though not the absolute certainty, that the rapid growth of the industrial countries will benefit the less developed countries by increasing the demand for their exports, by making a more liberal supply of capital and aid funds possible and, taking a broader and longer view, by developing numerous new technologies and products, many of which are extremely useful for the less developed countries. It is nevertheless necessary to dwell on the matter and carefully to establish the meaning, validity, and implications of the above statement because it runs counter to widely held pessimistic views. The extreme form of these heretical doctrines—heretical to the classical as well as the Keynesian theory—is represented by the transference to the international sphere of the Marxian theory of "increasing misery" (*Verelendungstheorie*). Since it really makes no sense any more to say that the American, European, or Japanese workers are getting poorer all the time, modern

Marxists have given up this theory for the developed countries. But it has survived in the international sphere. Thus Paul Sweezy admits that in the developed countries workers have a "tolerable if degraded life"; but the advanced countries "increasingly impose the burdens on the people of the colonies and the raw-material-producing countries" [21, p. 221]. A somewhat less extreme theory has been put forward by non-Marxist writers. Thus Gunnar Myrdal holds that "trade operates (as a rule) with a fundamental bias in favor of the richer and progressive regions (and countries) and in disfavor of the less developed countries." His thesis is not only that the poor countries derive less benefits from trade than the rich, but that, in the absence of strong protective policies, the poor become poorer if and because the rich get richer.<sup>15</sup>

Baldly stated like that, these extreme views are not widely accepted, but their influence in coloring the general thinking on these problems, especially in the less developed countries, should not be underrated. However, since they have been adequately criticized in the literature, I shall not discuss them further [13] [2].

The moderate version of the pessimistic view concerning the international position of the underdeveloped countries asserts that these countries have had no, or only a very inadequate, share in the expansion of world trade and that their international position has deteriorated continuously for the last ten years as evidenced by the lagging volume of exports and unfavorable terms of trade.

Looking at the broad facts, we find indeed that while the volume of exports and imports of the developed countries has grown at an annual rate of about 7 per cent from 1950 to 1960, the volume of exports of the "developing countries" (the official U.N. designation of less developed countries) has grown by 3.6 per cent and that of their imports by 4.6 per cent during the same period.<sup>16</sup> During the same period, the terms of trade of the developing countries in the aggregate have deteriorated by about 9 per cent as a consequence of a rise of about 10 per cent in unit value of the imports of the developing countries and a slight rise of unit value of their exports.<sup>17</sup>

<sup>15</sup> See [15]. Myrdal's policy conclusions are, of course, not the same as the Marxists'.

<sup>16</sup> See [22, p. 1]. Developed countries are North America, Western Europe, Australia, Japan, New Zealand, and South Africa. Developing countries are the rest of the world, excluding the "centrally planned economies" (Communist countries) in Europe and Asia.

<sup>17</sup> Measured from the peak in 1951 caused by the Korean War boom and massive U.S. stockpiling, the deterioration in the terms of trade would be substantially greater—14 or 16 per cent. The fact that the deterioration reflects a rise in import prices rather than a fall in export prices is significant because unit values of manufactured goods have a notorious upward bias, due to the fact that the gradual improvements in quality and the continuous appearance of new manufactured products are not, or very insufficiently, taken into account. In other words, a rise in import prices (of manufactured goods) is much less "real" than a fall of export prices (of primary products) would be.

To speak of developing countries in the aggregate—or, what comes to much the same thing, of a “typical” or “representative” underdeveloped country—is, of course, a bold abstraction from which purists will recoil in horror. The less developed countries are a much more heterogeneous group than the industrial countries. Among them there are semideveloped and wholly undeveloped countries; tropical and temperate zone agricultural countries; petroleum, mining, and agricultural product exporters; many pursue inflationary policies of varying degrees of severity, others are more disciplined; a few have convertible currencies but the majority suffer from overvalued currencies and their trade is restricted and distorted by controls and multiple currency practices of varying impenetrability.

In view of this great diversity of basic structures and policies, it is not surprising that the trade and growth performance of the less developed countries is very widely scattered. To search for systematic connections between the latter—performance—and the former—basic structures and policies—would be a challenging task but cannot be undertaken in one lecture. It would seem possible, however, to draw some useful conclusions from the over-all picture.

The most important fact is that the volume of trade of the less developed countries has grown and is growing at a substantial rate. The more rapid growth of the volume of imports than that of exports reflects the fact that these countries have been able to attract capital and have received substantial aid from the industrial countries.

This on the whole favorable picture is not changed by the fact that trade of, and between, the industrial countries has grown faster. The more rapid growth of the trade of industrial countries is not a new phenomenon. Even before 1914 it has often been observed, especially by free trade economists with obvious satisfaction, that “the industrial countries are their own best customers.” But during the Great Depression trade in manufactured products (which can be taken as a rough index of trade of developed countries) contracted more sharply than the volume of trade in primary products.

There are, however, good reasons to believe, as Professor Samuelson recently reminded us [17, p. 48], that lower total volume of trade between the developed and underdeveloped countries may bring more material benefits and consumer satisfaction to both partners than the larger volume of trade between the developed countries. The reason is that the intramarginal cost differences underlying the trade of manufactures between industrial countries are probably much smaller than those of which the trade between industrial countries and the exporters of primary products is based.<sup>18</sup>

<sup>18</sup> Alfred Marshall has alluded to that; Richard Schueller in [18] has commented on this

There is another factor involved. One of the reasons for the lower rate of growth of the trade of the less developed countries is surely that practically all of them pursue highly protectionist policies. In my opinion, they are going in their protectionism far beyond what can possibly be justified on infant-industry, terms-of-trade, or any other rational grounds. But whether one accepts this judgment or not, high protection reduces the volume of trade<sup>19</sup> and by the same token increases the *marginal* benefit from trade.

As for the terms of trade, the deterioration from the early 1950's is, of course, regrettable in the sense that the less developed countries would be better off if in 1960 their terms of trade were the same as in 1950. But we must keep a sense of proportion. The deterioration was not catastrophic and cannot be compared with what happened in the 1930's. The comparative order of magnitude is indicated by the fact that while, according to the U.N., from 1950 to 1960 the deterioration was 9 per cent, Kindleberger found that in 1938 the terms of trade of industrial Europe with a large part of the underdeveloped world stood at 149, with 1928 = 100 [22] [6].<sup>20</sup> To convey an idea of the absolute magnitude of the "burden" or "loss" involved, let me mention that the U.N. report computes that "had the terms of trade of the less developed countries been stabilized at their 1950 level the aggregate purchasing power of their exports in terms of imports in 1960 would have been greater to the extent of \$2.3 billion." This is not a negligible sum, but compared with the national income of the less developed areas of the

---

fact. See also D. H. Robertson [16]. It should be observed, however, that freer trade between the industrial countries, although it may be less valuable than trade between industrial and tropical countries on comparative cost grounds, can be beneficial through stimulating competition and counteracting monopolistic tendencies. This effect of free trade has been stressed by J. S. Mill and reiterated by modern theorists of integration, e.g., by Tibor Scitovsky and Harry Johnson.

<sup>19</sup> In underdeveloped countries the theory has been widely accepted that in less developed countries import restrictions do not reduce the volume of imports or exports; they merely cause a shift of imports from, say, luxury goods to capital goods. In the developed industrial countries, it is said, the classical rule still applies that import restrictions reduce the volume of trade in both directions. This is the official doctrine of the U.N. Economic Commission for Latin America (ECLA). See, e.g., [23, esp. p. 61]. The reason usually given is that these countries spend all their export proceeds anyway. This, of course, overlooks that protection draws factors of production into the protected industries from the export sector. Only under extreme and entirely unrealistic assumptions concerning the existence of large masses of disguised unemployment (including that of skilled workers), of surplus capacity, and very elastic capital supply could the conclusion be overthrown that export supply will contract as a consequence of massive import substitution brought about by heavy protection.

<sup>20</sup> Kindleberger's figures are not quite comparable with the U.N. figures because his area breakdown is a different one. The figure quoted in the text refers to industrial Europe's terms of trade with "all other areas," i.e., the world excluding the rest of Europe, the United States, and the "countries of recent settlement." With the last-mentioned area the index of industrial Europe's terms of trade stood at 138 in 1938 (1928 = 100).

world or its annual increase it is quite small.<sup>21</sup> The incidence of the 9 per cent over-all deterioration of the terms of trade on different areas was, of course, very uneven. Latin America, for example, suffered a deterioration almost double the average, the Middle East none at all, and the rest of Asia (excluding Japan) one much smaller than the average. But even in the area hardest hit—Latin America—the “importing power of exports” (volume of exports multiplied by terms of trade, also called “capacity to import”) has substantially increased throughout the period of 1950 to 1960 [4, p. 61]. As has frequently happened in the past, the impact of the change in the terms of trade on the primary exporters was partly offset by a sharp decline in freight rates which were very high in the early 1950's.<sup>22</sup> Since the middle of 1962, the international trade situation of the less developed countries has improved greatly, prices of many primary products have risen substantially, the terms of trade did not show any further deterioration, and export earnings have registered sizable increases.

Nobody can be sure how long that improvement will continue and how far it will go. But assuming that the industrial countries avoid serious depressions and maintain a good rate of growth, barring further revolutionary technological changes (such as the invention of cheap synthetic coffee) and highly protectionist policies on the part of the industrial countries—under these not unreasonable assumptions the less developed countries can look forward to a continuously expanding market

<sup>21</sup> Some may question the relevance of a comparison with national income. In my opinion, it is relevant with certain qualifications: A large and sudden change in the terms of trade might cause serious transitional difficulties. Or, if a country by extreme protectionism has reduced its imports to a bare minimum and has neglected its export industries, a decline in the terms of trade may necessitate a further reduction of imports which have already been stripped to essentials. In that case the impact on GNP would be out of proportion to the money cost of the deterioration quoted in the text because the “marginal benefit” of imports would be much higher than the marginal benefit of domestic production. If my income falls by 5 per cent and I were forced to skimp on food rather than spread the shortfall over the whole range of expenditures, the result would be disastrous. But I doubt whether any country really finds itself in such a predicament, although extreme protectionism could conceivably put it there.

<sup>22</sup> Charles Kindleberger has pointed out to me that a veritable revolution has taken place in ocean transportation. Thus, while the world wholesale price index in dollars has about doubled since before the war, oil tanker rates are just about where they were, and dry cargo rates have gone up on a very rough average by 50 per cent. This great cheapening of transport cost constitutes a powerful integrating force in the world economy and has bestowed great benefits, especially on many less developed countries, by improving their f.o.b. terms of trade.

The drastic reduction in transport cost, made possible by technological advances, applies primarily to the very competitive international routes. Many countries rob themselves of those very large benefits by highly protectionist shipping policies. This is especially true of coastal shipping, including sometimes shipping between neighboring countries. For example, freight rates between Rio de Janeiro and Buenos Aires are often as high as between Buenos Aires and New York, because of nationalistic policies. See [8, p. 297].

The jet aircraft promises to produce another revolutionary advance in transport technology.

for their exports, and a sharp deterioration of their terms of trade comparable to what happened in the 1930's is virtually excluded.

I should add that this fairly optimistic appraisal relates only to the international trade position of the less developed countries.<sup>28</sup> Far be it from me to belittle the severe handicaps from which many less developed countries suffer, such as poor natural resources and bad climate, population pressure, political and social instability, and, I am afraid one has to add, exceedingly bad economic policies. All I have said was that a shrinking or stagnant world market has not been among the handicaps since the war.

### VII. *Outlook for the Future*

Instead of summarizing what I have said, let me try to peer a little into the future. Since economists are not endowed with the gift of prophecy, I shall not try to predict what will happen to world trade in the future but do the next best thing and suggest what would be the course of events if certain conditions are fulfilled.

I see no reason why the the growth of world trade and the ever closer integration of the major areas of the world should not continue if two conditions are met. The first, basic requirement is maintenance of a high level of employment and growth in the industrial countries. On this nothing more need be added, except to say that to me the chances look good that this condition will be fulfilled. But it is a necessary, not a sufficient, condition. At least in the larger countries economic activity could grow quite satisfactorily (although not at the highest attainable speed) without a corresponding growth of trade.

The second presupposition is further liberalization of trade or, as a minimum, avoidance of increases in trade barriers for balance-of-payments or protectionist reasons. I am afraid we cannot be so sure about this condition being met as about the first. Balance-of-payments

<sup>28</sup> W. Arthur Lewis has reached similar conclusions in two important papers [9] [10]. Speaking of Latin America, he said: "Puzzling are those cries which seem to be founded on the belief that it is particularly difficult to expand exports because the world is buying fewer and fewer exports. The opposite is true. World trade has never grown faster. Between 1950 and 1960 the quantum of world trade in primary products increased at an average rate of 6 per cent per annum, and the quantum of world trade in manufacturers by more than 7 per cent per annum. The terms of trade for primary products could not retain the heights to which they were raised by the speculative fever of the Korean War and the heavy American stockpiling in the early fifties; nevertheless the average terms of trade for the decade of the nineteen-fifties were better than for any previous decade in all the preceding hundred years. I do not know whether it is in fact true that in the 1950's, Latin America had difficulty in keeping her exports growing at the same rate as national income but if this was so, it cannot possibly have been due to failure of world demand to grow adequately, since the quantum of world trade was growing by about 7 per cent per annum throughout the 1950's. Taking the continent as a whole, rather than individual countries, failure on this score can only have been a failure of effort" [10, pp. 10-11].

troubles among industrial countries could easily become a serious road-block to freer trade, as is already the case to some extent in the United States through the tying of loans, buy-American policies, and similar protectionist devices. Paradoxically, attempts at regional integration in various parts of the world constitute an imminent danger to world-wide integration and further growth of multilateral trade.<sup>24</sup>

As to the balance of payments, I must confine myself to a few remarks. The current American difficulties will somehow be resolved, but will hardly remain the last case of serious disequilibrium among the industrial countries. With the rate of growth slowing down and inflation going on in some countries, with anti-inflationary and growth-promoting measures being taken in different countries with different degrees of vigor and success, it would be very surprising indeed if strains in the international payments system did not develop from time to time in different places.

The extreme reluctance to change any exchange rate and the stubborn rejection of floating rates not only for reserve currencies, which is understandable, but also for nonreserve currencies throw a very heavy burden on internal price and wage adjustments. The successful operation of the present system requires, if world-wide inflation is to be avoided, a degree of financial and wage discipline which few countries have so far been able to muster.<sup>25</sup> But the problem is not insoluble and, since the imposition of financial and wage discipline is, after all, the most important advantage that can be claimed for the system of stable exchange rates, we can only hope that sufficient discipline will in fact be forthcoming to bring about the necessary adjustments smoothly and speedily without causing severe restrictions of trade or serious unemployment in the process.

I suppose I have to mention international liquidity. I can only say that it does not strike me as a problem of major importance or difficulty. The policy-makers have a great number of plans to choose from—Bernstein, Posthuma, Roosa, Triffin, Zolotas, to mention only a few luminaries. Even the more modest ones would banish the danger of a general lack of liquidity, at least for many years. I wish, therefore, that a large part of the professional ingenuity that is now being spent so lavishly on that issue were diverted to the basic and much more difficult problems of internal price and wage restraints and adjustments.

<sup>24</sup> Another acute danger, which cannot be discussed here, is regimentation, contraction, and distortion of trade through the numerous international price-support schemes of important commodities now under active consideration.

<sup>25</sup> I would agree that a floating rate system, too, requires price and wage discipline for successful operation. But I would argue that the fixed rate system calls for much sterner discipline.

The regional integration schemes that are now in the process of realization have developed strongly protectionist features which go far beyond their unavoidable discriminatory effects. This is true of the European Common Market and even more so of its Latin American counterpart. In fact, as far as the latter is concerned, it is an understatement to say that protectionist tendencies have appeared. The Latin American Free Trade Area (LAFTA) has been conceived openly and frankly as a protectionist device from its beginning.<sup>24</sup> On the other hand, many of the managers and supporters of EEC inside and outside the six members sincerely regard the Common Market as a step towards freer trade. But good intentions even on the part of the managers are not enough. An international enterprise of that magnitude, once it has been launched with a tremendous effort and enthusiasm and has been institutionalized through the creation of a heavy politico-bureaucratic machinery, tends to develop its own logic and movement. After it has gathered momentum, it becomes very difficult to steer it in another direction. This has been discovered, to their sorrow, by the vocal and vigorous forces which, working from within and from without EEC, have been trying to persuade the Community to adopt an "outward looking attitude," as the phrase goes. A crucial test as to whether or not it can be made to move in the direction of freer trade will come next year when the negotiations begin in earnest on the so-called Kennedy-round of tariff reductions in Geneva.

Let us hope that this noble experiment will succeed, that tariffs between the industrial countries and on imports from the less developed countries will be drastically reduced. Then the future economic historian will be able to say of the European Economic Community what Marshall said of the German *Zollverein*—it was a big step toward freer multilateral trade.

<sup>24</sup> This does not necessarily mean that it is undesirable. There are valid arguments for protection which theoretically can be applied to customs unions or free trade areas. In the case of LAFTA, the protectionist effects are, however, so strong that it would be very difficult to make a rational case for it on, say, infant-industry grounds. It could conceivably be defended with the help of a theory of the third or fourth best. Let me briefly indicate what I have in mind. By means of a policy of partly repressed inflation, tight exchange control, etc. a country can maneuver itself into a position where trade is so sharply contracted and distorted that even bilateral trade is better than no trade. Similarly, a regional trade expansion may be better than no expansion at all, although a relaxation of controls and general expansion of trade would be infinitely better.

## RULES OF THUMB AND OPTIMALLY IMPERFECT DECISIONS

By WILLIAM J. BAUMOL AND RICHARD E. QUANDT\*

It is easy to jump to the conclusion that the widespread use of rules of thumb is good evidence of sloppy workmanship on the part of business management. We shall argue in this paper that, on the contrary, rules of thumb are among the more efficient pieces of equipment of optimal decision-making. We shall therefore investigate in fairly general terms how "good" rules of thumb can be designed and evaluated. The paper also reports on an illustrative application of the analysis. A simulation procedure is used to determine the relevant properties of a number of alternative pricing rules of thumb and to compare their performance as guides to decision-making in a single-product monopolistic firm.

### I. *Optimally Imperfect Decisions*

The more refined the decision-making process, the more expensive it is likely to be, and therefore, especially where a decision is not of crucial importance, no more than an approximate solution may be justified. Since all real decisions are made under conditions of imperfect information, calculation down to the last decimal place is pointless in any event. One can easily formulate the appropriate (though not very helpful) marginal condition for what one may call an *optimally imperfect decision*, which requires that the marginal cost of additional information gathering or more refined calculation be equal to its marginal (expected) gross yield. The expenditure of any further effort in this direction can be ascribed only to miscalculation of its returns or its costs or to what one economist has happily described as "an irrational passion for dispassionate rationality."

There seems to be a close affinity between this position and Professor Simon's view that the businessman's goal can be better described as "satisficing" than as some sort of maximization. Simon appears to be asserting, in effect, that businessmen usually do not even attempt to

\* The authors are, respectively, professor and associate professor of economics at Princeton University. They would like to acknowledge their gratitude to the National Science Foundation, whose grant to their study on the dynamics of the firm enabled them to complete this paper. They are also indebted to Professor H. W. Kuhn and Messrs. H. Shapiro and L. Sydor for their very constructive advice and to Mr. F. Foulkes for assistance with the computation. Most of the calculations were performed on a CDC-1604 Computer.

find maximal solutions<sup>1</sup> precisely because they recognize the limited accuracy of their information and excessive costs of persnickety calculation, and that, instead, they are well satisfied with viable solutions to their problems.<sup>2</sup>

For the purposes of this paper we define a rule of thumb to be a set of rules describing a decision procedure with the following characteristics:

(a) The variables which are employed in the decision criteria are objectively measurable.

(b) The decision criteria are objectively communicable, and decisions do not depend on the judgment of individual decision-makers.

(c) As a corollary to (b), every logically possible configuration of variables corresponds to a (usually unique) determinate decision.

(d) The calculation of the appropriate decision is simple, inexpensive, and well suited for frequent repetition and for spot checking by management in higher echelons.

A decision process with these characteristics seems to be designed as the instrument par excellence of optimally imperfect decision-making for routine and recurrent problems.<sup>3</sup>

## II. *Optimal Rules of Thumb: Definitional Problems*

Even conceptually, the ranking of rules of thumb is not as easy as one might think because problems of multidimensionality are inherently involved.

It may at first glance seem sufficient to say that, of two rules which are equally costly to operate, the one which yields the closer *average* approximation to the true maximum is to be preferred. But some measure of the dispersion of the results is, surely, also of comparable relevance. In fact, all the characteristics of the frequency distribution of errors are significant. The "best" rule of thumb can only be determined by taking all of these characteristics into account and assigning appropriate weights to them.<sup>4</sup>

<sup>1</sup> For our purposes it is convenient to distinguish between a *maximal* and an *optimal* solution. The former term shall be used throughout this paper to connote the exact solution which would be obtained if there were no data limitations or calculation costs, while the term "optimal solution" refers to the ideal approximation to the maximal solution.

<sup>2</sup> See e.g., Herbert Simon [5]. Simon is, of course, saying considerably more than this—he is proposing the hypothesis that businessmen, at least implicitly, set up a number of criteria of satisfactory performance and are willing to accept any decision that passes these tests. It is, as it were, constrained maximization with only constraints and no maximization!

<sup>3</sup> Note that the operations researcher's strategy is usually to replace his client's current rules with some others which he considers more satisfactory, *but which remain rules of thumb nevertheless*.

Moreover, even in computer simulation models, where the world is considerably simplified, and information gathering and refined calculations are relatively cheap and easy, it has in many cases proved impossible even for the sophisticated designers of the models to have their "firms" operate by means other than rules of thumb.

<sup>4</sup> The assignment of weights is, of course, equivalent to determination of an appropriate utility function.

It would appear to follow that there is no cut and dried mechanical way of determining which of two rules is the more satisfactory unless one of them is what might be called "Pareto preferable," that is, it is not inferior in any of its relevant characteristics and superior at least in some.<sup>5</sup>

Another difficult problem, intrinsic to the search for an optimal rule of thumb, arises out of the need to specify the range of alternatives to be tested. In other types of decision this task is sometimes fairly simple, as in a decision problem consisting in a choice of the (numerical) value of a variable, where one need at most specify the end points of the range to be considered.

But in selecting a rule of thumb we are to choose not a number but a functional relationship. For example, inventory might be regulated either by a usual business rule of thumb,  $I = kS$ , or by the simplest inventory theoretic rule,  $I = \sqrt{aS}$  (where  $I$  is the level of inventory,  $S$  is sales volume per unit of time, and  $k$  and  $a$  are constants), or it can be determined by any of a variety of alternative simple expressions. Unfortunately, there is no obvious way to supply a reasonably representative list, let alone an exhaustive list of such possibilities.<sup>6</sup>

### III. Calculation Problems

A crucial step in the determination of an optimal rule of thumb is the calculation of the expected consequences of the adoption of any particular rule of thumb. Ideally, this step should produce a frequency function of the errors to be expected of any such rule of thumb in its approximation to true maximal solutions.

In principle, it may be possible to determine these frequency functions analytically if the structure of the system and the probability distributions of the structural variables are known. However, in practice, such a procedure is almost always impossible. First, an a priori specification of probability distributions for the structural variables usually represents most heroic assumptions that rarely stand up under comparison with the facts. Secondly, even under these conditions, analytic methods of determination of the expected effects of a rule of thumb are likely to be prohibitively difficult.

This means that one must turn to some alternative methods of testing and calculation. The methods of simulation using artificial data and of "dry run" testing on the basis of past history seem well suited to

<sup>5</sup> It is worth noting that the possibility of intransitivity is one of the unpleasant consequences of the multidimensional character of the comparison of several rules of thumb. This is entirely analogous with the paradox of voting, and can arise whenever the choice of rule of thumb is decided by determining which of the candidate rules has a majority of preferred characteristics. For a discussion of the paradox of voting see Arrow [1, pp. 2-3].

<sup>6</sup> This observation also indicates a difficulty inherent in the optimality calculation. Because, in selecting a rule of thumb, one chooses a function rather than a value of a variable, the problem falls within the difficult territory of the theory of functionals.

the problem. By considering a sufficient number of simulated cases the analyst may be able to come away with a fair idea of the rule's likely performance. Unfortunately, invented case histories are apt to be very poor approximations to reality or they may constitute a biased selection out of the set of possibilities. Moreover, to test how well the rule of thumb performs, one must be able to compare it with the true maximal solution in the selected cases. In models that are somewhat complicated this is not always possible.

The alternative to simulation is a procedure for testing the rule with the aid of a number of cases appropriately selected from actual past experience. This procedure reduces the danger of selection of artificial and excessively simple or unrepresentative test cases, but it is perhaps even more likely than is a simulation to result in difficulties in computing the true maximum.<sup>7</sup>

#### IV. *Approaches to an Optimality Analysis*

Though, as emphasized in Section II, there exists no systematic method for specifying all the rules of thumb which should be tested in any particular case, the matter is not completely hopeless. Many functions can be approximated fairly well, at least for limited ranges of the independent variables, by one of a small set of simple algebraic functions, such as equations of the conic sections, polynomials of reasonably low degree, logarithmic functions, and so on.

This approach, combined with a simulation or a statistical estimation and testing procedure, can sometimes be used to generate rules of thumb that may plausibly be expected to yield a fair degree of approximation to the true maximum. That is the basic method employed in this paper.<sup>8</sup>

Before turning to our application of this method, it is appropriate to mention an alternative and promising approach to the selection of rules of thumb which is based on the use of axiomatic methods.<sup>9</sup> In effect, this procedure gives up the search for a truly maximal solution. Rather, it specifies sets of acceptability conditions, in the form of axioms, which serve as constraints capable of narrowing down the range of possible

<sup>7</sup> Fortunately, these problems are not always very serious. For example, in one statistical study based on actual records of approximative rules for transportation-routing decision-making the calculations were relatively straightforward, and rather definitive conclusions were obtained as to which of the proposed rules gave the best performance. See Kuhn and Baumol [3].

<sup>8</sup> We have also used it in other connections. For example, in one unpublished inventory investigation, numerical methods were employed to determine the least-cost inventory levels for a number of alternative sales levels. It was then found that the exponential expression  $I = cS^b$  provided a very good fit to the results but for a value of  $b$  considerably different from the 0.5 exponent of the standard simplified inventory theory relationship  $I = \sqrt{aS}$ .

<sup>9</sup> Thus it is possible to interpret the Chernoff or the Milnor approaches to the decision problem as illustrations of rule-of-thumb selection. See Chernoff [2] and Milnor [4].

solutions.<sup>10</sup> For example, in setting up a reasonably simple decision rule of thumb it may be proposed that any such rule which does not yield a transitive relationship is completely unacceptable. By a sufficiently skillful selection of such a set of requirements it is sometimes even possible to arrive at a unique solution, which, if it is simple enough in form, may then be adopted as the desired rule of thumb.

### V. Designing a Price-Setting Rule

Let us turn now to an illustrative application of our proposed procedure, to one of the microeconomist's favorite subjects—the price setting of a retail firm. The performance of a number of alternative pricing rules of thumb was tested by a simulation process employing a considerable number of artificial randomly generated demand and cost functions.

In planning the analysis several alternative types of pricing rules were considered for testing:

(a) *Markup rules* which set price by means of a more or less fixed markup over wholesale cost, as is apparently done in a variety of retailing establishments.

(b) *Imitative rules* in which each firm seeks to keep its price at the level set by its competitor. Such rules would fit in with the standard kinked-demand-curve analysis and are compatible with such observed retailing institutions as comparison shopping.

(c) *Learning rules* whereby, if a firm raises its price and then finds its profits have increased, it raises price again; while, if its profits have fallen, in the next period it lowers its price.

(d) *Pseudo maximizing rules* in which simple demand and cost curves are crudely fitted by quick and inexpensive methods to recently observed data and, from these simple curves, an approximative profit function is derived and used to determine the price formula (rule of thumb) which maximizes the value of that approximative function.

Our analysis was confined to the last of these four categories, the pseudo maximizing rules of thumb. Our approach proved to be totally unsuited to analysis of the first two types of rule. Testing of fixed markup rules requires some knowledge of the relationship between wholesale cost (which is the basis for the markup price) and the operating costs of the retailer (which must affect the profit-maximizing price). If the two types of cost bear only a random relationship to one another,

<sup>10</sup> Note the resemblance of the entire approach to Simon's satisficing hypothesis (see [5]). Sometimes the acceptability constraints are so demanding that they eliminate the feasible region altogether, so that no solution can possibly satisfy the acceptability conditions. An excellent illustration is the Arrow possibility theorem [1, Ch. 5]. In other cases the acceptability conditions will not be sufficiently strong to reduce the set of possibilities to a single choice. In that case the axiomatic approach may still have to be supplemented by some sort of optimality calculation which chooses among the remaining possibilities.

it is clear that a fixed markup price would be randomly related to the maximizing price.<sup>11</sup> In reality, the two types of cost are, no doubt, closely interconnected, but there seems to be no way in which this relationship can be captured by the random-number cost-generating mechanism.

We did not study pricing rules of type b (imitative pricing) for similar reasons. Imitation implies the presence of someone to imitate, and since we were generating data for only one firm, and not dealing with any sort of explicit oligopoly relationships, there was no way in which such rules could be investigated.

Rules of type c (the learning rules) could have been tested. We did not investigate these by simulation techniques because we felt the calculations had already gone far enough for our present purpose—illustration of a method of approach. However, a few observations on the properties and testing of such learning rules are offered in Appendix A.

The last type of rule of thumb, the type discussed in the remainder of this paper, is what we have called the pseudo maximizing rule. Details of each rule depend on the character of the functions used as estimates of the cost and demand functions. We considered four possible sorts of approximating function: linear, quadratic, logarithmic, and exponential. Of course, various combinations are possible—the demand curve can be linear and the cost curve logarithmic, etc. Thus 16 possible combinations were examined (and a few others in addition). Most of these were quickly abandoned because they required computations too complex to permit them to qualify as rules of thumb, and we emerged with four possibilities to use in our test.<sup>12</sup> Two other rather arbitrary “naïve” pricing rules were set up as standards of minimal performance.

We imposed one rather strong condition on the construction of our rules in order to assure that they were sufficiently simple to qualify as rules of thumb: in no case was the decision-maker asked to take account of more than two points on his demand curve and two points on his cost curve in his calculations. Very clearly this (intentionally) restricted us to

<sup>11</sup> Thus, it may be argued that the randomly chosen price rule of thumb (Rule 2) which we did test is the best approximation to a fixed markup rule that our analysis can achieve! The reason for our inability to test a markup rule can be made clearer in the simple case where marginal and average cost are constant and hence equal to one another. By the standard marginal revenue expression,  $MR = p(1 - 1/\epsilon)$  where  $\epsilon$  is the elasticity of demand. Hence, if price,  $p$ , is optimal so that  $MR = MC = AC$ , we must have  $p(1 - 1/\epsilon) = AC$ . The optimal markup over average cost is thus  $1/(1 - 1/\epsilon) - 1 = 1/(\epsilon - 1)$ . This well-known result shows that the optimal markup is constant only if  $\epsilon$  is constant. Moreover, a fixed markup price will have a random relationship to an optimal price so long as  $\epsilon$  is a random number. Similar arguments hold when  $MC$  is not equal to  $AC$ .

<sup>12</sup> Several other cases might have qualified. For example, the linear cost function  $D + Eq$  and the demand function  $p = A - Bq^{k-1}$  can readily be shown to yield the maximum pricing rule  $p = (kA - A + E)/k$ .

the crudest sort of approximation procedures, for we wanted to see how far one can get with such extremely imperfect tools.

### VI. *Description of the Experiments: the Cost and Demand Functions*

Before describing the details of our experiments, it is convenient to summarize the basic methods that were used. First, a demand (average revenue) curve facing the entrepreneur and his total cost curve are generated by a random process. The resulting pair of demand and cost curves are regarded as the "true" curves, describing correctly the actual state of affairs. The entrepreneur is assumed to know only two points on each of these curves. He uses some rule of thumb to calculate from these two pairs of points the price he is to charge in the market. We can determine from the true demand and cost curves the profit-maximizing price and the maximum amount of profit as well as the entrepreneur's actual profit resulting from his rule-of-thumb price. The comparison of actual and maximum profit provides an estimate of the efficiency of the rule of thumb.

The detailed discussion of our basic experiments can conveniently be divided into three parts: (1) the methods that were used to generate demand and cost functions, (2) the rules of thumb that were employed, (3) the method that was used to obtain estimates of the performances of various rules of thumb.

1. *The demand (average revenue) function.* The hypothetical product we deal with is assumed to be such that the quantity demanded is zero when the price,  $p$ , is greater than or equal to 21. The demand function (as well as the cost function) is discrete. The quantity demanded is defined only for integral values of  $p$ . The demand function was obtained by requiring the graph to start off at the point with coordinates  $p=21$ ,  $q=0$  and then calculating *increments* in the quantity demanded corresponding to successive unit reductions in the price. The increments were selected in one of two ways:<sup>13</sup> (i) in Runs 1, 2, 3, 4, and 5 the increments are uniformly distributed over the integers 1, . . . , 64; (ii) in Run 6 the  $i^{\text{th}}$  increment is  $X_i + 2i$  where  $X_i$  is uniformly distributed over the integers 1, . . . , 64. Note that the total revenue function need not be concave everywhere, and that a finite amount is demanded when the price is zero.

<sup>13</sup> These two methods generate demand functions whose expected values are, respectively, linear and quadratic. That is, in Runs 1-5, with each unit increase in price the expected (average) decrease in demand is  $(1+2+\dots+64)/64=32.5$ . Hence the expected  $dq/dp$  is constant and the expected demand curve is linear. In Run 6 the expected sales increment when price is  $p=21-i$  is  $\Delta q=32.5+2i$ , so that we can take  $\Delta q/\Delta p=-32.5-2i$  (approx.), and hence the expected demand function generated in Run 6 is quasiquadratic. Similar interpretations hold for the cost functions that were used in the various runs. More information about the nature of these functions is given in Appendix B.

2. *The total cost function.* The demand function was obtained by associating with each price,  $p$ , a quantity  $q=f(p)$ . The cost function associates with each of these  $q$ 's a total cost figure  $C=g(q)$ . With zero output we associate a cost figure which is chosen from the uniform distribution over the integers 1, . . . , 64. Each successive cost figure (associated with the successively higher output levels) is obtained from the immediately preceding one by the addition of an increment. Depending on the run, the  $t^{\text{th}}$  increment is (i) chosen from the same distribution, (ii) a multiple of an increment chosen from the same distribution, or (iii) expressible as  $Y_t+8t$  where  $Y_t$  is chosen from the same distribution.

It is obvious that maximum profit and the optimal price are easily determined from these functions, simply by examining in turn, each of the 22 possible price levels ( $p=0$  to  $p=21$ ) and calculating, in each case, the associated profit figure. The six experiments are summarized in the table below, showing the manner in which the  $t^{\text{th}}$  increments for the demand and cost functions were generated. Letting  $X_t$  and  $Y_t$  be random variables distributed uniformly over the integers 1, . . . , 64, we have:

	Demand function increment	Cost function increment
Run 1	$X_t$	$Y_t$
2	$X_t$	$4Y_t$
3	$X_t$	$8Y_t$
4	$X_t$	$Y_t+8t$
5	$X_t$	$4Y_t+8t$
6	$X_t+2t$	$Y_t$

3. *Entrepreneurial estimates of the demand and cost functions.* For the purpose of calculating rule-of-thumb solutions to the profit-maximization problem we assumed that, on the basis of recent experience, the entrepreneur knew exactly two points on his demand function and two points (with the same abscissae as the points on the demand function) on his cost function. The entrepreneur was then assumed to calculate his pseudo optimal price on the basis of the information contained in these four points. It is to be noted that if the pseudo optimal price,  $\hat{p}$ , turned out to be fractional, it was rounded to the smallest integer greater than  $\hat{p}$ . The profit accruing to the entrepreneur under a particular rule of thumb was then calculated from the true demand and cost functions.

It is clear that the entrepreneurial estimates of the demand and cost functions will depend, in general, upon which two of many possible points on the demand and cost functions the entrepreneur is assumed to

know. In order to evaluate the *average or expected* effectiveness of a rule of thumb statistically, the experimenter must therefore present the entrepreneur, seriatim, with various alternative pairs of points and observe his behavior in each of these possible cases. The manner in which such pairs of points were selected for the purposes of the experiment is described in Section VIII.

### VII. *The Rules of Thumb*

The six rules of thumb which were investigated were chosen essentially on the basis of their (relative) simplicity. No attempt was made a priori to choose rules which would in some sense be highly reasonable. In particular, the first two of the rules which are about to be described may be considered totally arbitrary and unreasonable. These "naïve rules" were designed only to provide minimum standards of performance, in that any rule which does not provide results better than those offered by our naïve rules should, doubtless, be rejected out of hand.

(*Naïve*) *Rule 1. Fixed price.* Irrespective of the location of the two known points on the demand function and the cost function, charge a price  $p=11$ , which is the midpoint of the range of relevant positive prices. Strictly speaking, this is not even a rule of thumb under our definition because no decision machinery is provided whereby the decision-maker can actually select his unvarying price on the basis of objectively measurable data.

(*Naïve*) *Rule 2. Random price.* Choose a price from the uniform distribution over the integers 3, . . . , 17, irrespective of the two known points from the demand and cost functions.

*Rule 3. Linear demand, linear cost.* Fit to the two known points on the demand function the linear relation  $p=a-bq$ , and to the two points on the total cost function the linear relation  $c=d+eq$ . If the two pairs of points are given by  $(p_1, q_1)$ ,  $(p_2, q_2)$  and by  $(c_1, q_1)$ ,  $(c_2, q_2)$ , estimates of  $a$ ,  $b$ ,  $d$ , and  $e$  are obtained from the expressions

$$b = \frac{p_1 - p_2}{q_2 - q_1}$$

$$a = p_1 + bq_1$$

$$e = \frac{c_1 - c_2}{q_1 - q_2}$$

$$d = c_1 - eq_1.$$

Here, for example, the expressions for  $b$  and  $a$  are obtained directly by elimination from the two equations  $p_1 = a - bq_1$  and  $p_2 = a - bq_2$ . The entrepreneur is then assumed to calculate his pseudo optimal price

by maximizing profit on the basis of the estimated demand and cost functions. Profit is

$$\pi = aq - bq^2 - d - eq,$$

and maximizing,

$$\frac{d\pi}{dq} = a - 2bq - e = 0$$

so that

$$q = \frac{a - e}{2b}$$

and, from our demand equation,<sup>14</sup>

$$p = a - b \left( \frac{a - e}{2b} \right) = \frac{a + e}{2}.$$

By virtue of the method by which the true demand function is generated,  $b > 0$  and the second-order condition for a maximum is always satisfied.

*Rule 4. Linear demand, quadratic cost.* In Rule 4 the demand function was estimated in the same manner as in Rule 3. The cost relationship fitted was the quadratic function  $c = dq + eq^2$ . The coefficient estimates were given by

$$\hat{e} = \frac{c_1 q_2 - c_2 q_1}{q_1 q_2 (q_1 - q_2)}$$

$$\hat{d} = \frac{1}{q_1} [c_1 - \hat{e} q_1^2].$$

Maximizing profit

$$\pi = aq - bq^2 - dq - eq^2$$

yields the first-order condition

$$\frac{d\pi}{dq} = a - 2bq - d - 2eq = 0$$

<sup>14</sup> The clerk who actually makes the rule-of-thumb calculation does not have to make an explicit estimate of the demand and cost equations to determine price. From our next equation we have  $p = (a + e)/2$  and so, substituting the preceding estimating expressions for  $a$  and  $e$ , we obtain  $p = (p_1 q_2 - p_2 q_1 + c_2 - c_1) / 2(q_2 - q_1)$ . This equation permits calculation of price directly in terms of the observed prices, cost and sales levels. A similar observation applies to our other rules.

whereby

$$q = \frac{a - d}{2(b + e)}, \quad \text{and} \quad p = a - b \left( \frac{a - d}{2(b + e)} \right).$$

The second-order condition is

$$2(b + e) > 0.$$

We observed the following conventions:

(a) Where the second-order condition failed (which can happen since  $e$  may be negative), a price  $p=21$  was charged.<sup>15</sup>

(b) If the calculated optimal quantity was nonpositive, a price  $p=21$  was charged.

(c) Marginal cost was constrained to be positive for the entire relevant range of outputs.

*Rule 5. Linear demand, logarithmic cost.* In Rule 5 the demand curve was obtained as before. But this time the cost function was

$$c = dq + e \log (q + 1).$$

From the two given points on the cost function, the coefficients  $d$  and  $e$  were estimated by

$$\begin{aligned} e &= \frac{c_1 q_2 - c_2 q_1}{q_2 \log (q_1 + 1) - q_1 \log (q_2 + 1)} \\ d &= \frac{1}{q_1} [c_1 - e \log (q_1 + 1)]. \end{aligned}$$

Maximization of the profit function

$$\pi = aq - bq^2 - dq - e \log (q + 1)$$

yields the first-order condition

$$\frac{d\pi}{dq} = a - 2bq - d - \frac{e}{q + 1} = 0,$$

whence

$$q = \frac{(a - d - 2b) \pm \sqrt{(a - d - 2b)^2 + 8b(a - d - e)}}{4b}.$$

<sup>15</sup> This convention and the corresponding conventions for Rules 5 and 6 may plausibly be considered to have introduced some bias against these rules in our final evaluation. For with  $p=21$ , sales are zero and profits negative; presumably in cases where a rule breaks down in so obvious a manner even a moderately intelligent clerk could often do better than that, so that it is probably unfair to credit these rules with no more than a zero profit contribution in these cases.

The second-order condition is

$$-2b + \frac{e}{(q+1)^2} < 0.$$

Various problem possibilities arise in this calculation, and they were handled by the conventions indicated below:

(a) Double roots. If the single distinct  $q$  was negative, a price of 21 was charged. If the single distinct root was positive but the second-order condition was not satisfied, a price of 21 was charged, yielding zero sales.

(b) If roots were complex, a price of 21 was charged.

(c) If the roots were real and distinct, a price of 21 was charged either if both roots were negative or if the single positive root corresponded to a minimum.

If a positive  $q^*$ , corresponding to a maximum of the profit function, existed, the entrepreneur charged the price  $p = a - bq^*$ .

*Rule 6. Hyperbolic demand, quadratic cost.* In Rule 6 the demand function is approximated by  $p = a - b/q$ , and its coefficients were estimated from the two "observed" points by

$$\hat{b} = - \frac{p_1 - p_2}{q_2 - q_1} q_1 q_2$$

and

$$\hat{a} = p_1 + \frac{\hat{b}}{q_1}.$$

The cost function was estimated as under Rule 4.

The profit function now is

$$\pi = aq - b - dq - eq^2$$

and, maximizing, we obtain

$$\frac{d\pi}{dq} = a - d - 2eq = 0,$$

yielding

$$q = \frac{a - d}{2e},$$

and the second-order condition is now

$$e > 0.$$

If either the second-order condition was violated or the pseudo optimal  $q$  was nonpositive, the pseudo optimal price  $p=21$  was chosen. Otherwise the entrepreneur was taken to charge

$$p = a - b \left( \frac{2e}{a - d} \right).$$

### VIII. *Methods of Testing*

As indicated earlier, Rules 1 and 2 yield results which are independent of the particular information assumed to be immediately available to the entrepreneur. Therefore one and only one rule-of-thumb solution is provided by each of these two rules for any given randomly generated demand function-cost function pair.

This is not the case with Rules 3, 4, 5, and 6. The particular solution obtained from these rules depends on which two out of the possible 22 points on the demand and cost functions are used in fitting the demand and cost functions.

We have assumed that a zero output or an output salable only at a zero price is never used by the entrepreneur in this calculation. Hence 20 points remain, out of which "nature" was taken to choose two for the entrepreneur to observe. In order to evaluate the performance of a rule of thumb we calculated its solution for each possible pair of points chosen out of the total of 20. There are 190 such pairs and therefore 190 profit figures corresponding to a single "true" demand function-cost function combination, i.e., to a single rule of thumb. For each particular true demand function-cost function combination we thus obtained the profit accruing under Rules 1 and 2, and each of these was compared with the *average* profit figure accruing under Rules 3, 4, 5, and 6.

Altogether, 24 different true demand function-cost function combinations were generated for each run.

### IX. *Results of the Calculations*

Table 1 contains a summary of the results of the calculations. The table is divided into six sets of rows, each set corresponding to one of the six runs, and seven columns, corresponding to true profit maximization and the six rules of thumb. In each set of rows corresponding to a particular run the first row contains the mean profit (for the 24 cases) under true profit maximization and the various rules of thumb; the second row records mean profit as a percentage of maximum profit; the third row contains the standard deviations of the profit expectations for the 24 cases; the fourth row reports the standard deviation divided by the mean; the fifth row contains the standard deviation over the 24 cases of the difference between maximum profit and mean profit achieved (a measure of *dependability* of the rule in approximating the

TABLE 1—SUMMARY OF RESULTS

	Max. Profit	Rule 1	Rule 2	Rule 3	Rule 4	Rule 5	Rule 6
RUN 1							
Mean Profit	3,398.2	3,204.7	2,350.8	2,980.9	2,971.8	2,985.0	223.5

maximum), and, finally, the last row indicates the least profit encountered in the 24 cases.

The figures in Table 1 suggest that Rules 2 and 6 can be eliminated immediately on the basis of their poor performance. Rule 2 does not perform badly in Run 1 but tends to be much worse in most later runs. The reason is that, because of the upward shift in the cost function in Runs 2-5, the average optimal price is higher in these runs; hence the average deviation (average mistake) involved in using Rule 2, which uses random price setting, tends to increase in the later runs. The hyperbolic demand function involved in Rule 6 is bad because the true demand function is pseudo linear (except in Run 6) in the sense that if, in generating the demand function, we replace the random element by its expected value, we would indeed obtain a set of points lying on a straight line. In fact, the various actual demand functions generated can be judged visually to be linear to a reasonable level of approximation. Fitting a hyperbolic function to a linear set of points (particularly on the basis of two points only!) is likely to lead to poor results.

The relatively good performance of naïve Rule 1 (especially in Run 1) is not as inexplicable as it may appear. It is largely an artifact of the nature of our simulated cost and demand functions, as is shown in Appendix B. Indeed, it was the surprising profitability of Rule 1 which indicated some of the biases of our simulation model and led to the analysis in the Appendix.

Rules 3, 4, and 5 involve linear demand functions and linear, quadratic, and logarithmic cost functions, respectively. Since the total cost function is generated in essentially the same way as the demand function, it is pseudo linear (except in Runs 4 and 5 where it is pseudo quadratic) and we would, on the basis of previous arguments, expect Rule 3 to perform best in Runs 1, 2, 3, and 6. In terms of mean profit this is not quite the case but, on any criterion, the performance of Rule 3 is difficult to distinguish from that of Rule 5. All three of these rules yield high average profits, Rules 3 and 5 providing the largest returns in Runs 1, 2, 3, and 6. In Runs 4 and 5 the cost function is pseudo quadratic, and Rule 4 performs best in terms of mean profit, as indeed it should. On the basis of other criteria they do quite well too. With the exception of Rule 6, profits under Rules 3, 4, and 5 exhibit the smallest standard deviations, indeed in most cases *smaller than the standard deviation of the true optimal profit figures*. In most cases (except Run 3, Rule 4) the standard deviation as a fraction of mean profit is of the same order of magnitude for Rules 3, 4, and 5 as for maximum profits. The standard deviation of the difference between mean and maximum profit is lowest (except for one minor exception) for Rules 3, 4, and 5 and varies from run to run in such a manner as to preclude an unambiguous ranking

of these three rules. The lowest profit figures produced by Rules 3, 4, and 5 are also relatively high, easily beating the alternative rules of thumb except in a few cases.

Thus Rules 3, 4, and 5 seem to be the best of our rules of thumb, whether judged on variability of profit yield or on the basis of the maximum criterion. On the grounds of simplicity and lowest cost of computation, Rule 3 comes out ahead because it uses only linear functions. It is noteworthy that the simplest rule is also among the best as judged by the other criteria.

It may be noted in conclusion that the performance of these rules of thumb in terms of mean profit is indeed remarkable in view of the fact that the profit calculations were based on demand and cost functions fitted only to *pairs* of points on the two functions. Since the demand and cost functions are pseudo linear or pseudo quadratic in the sense described, we would expect reasonably good estimates of the true functions when the estimation procedure involves a pair of points lying relatively far from one another. However, we would expect rather poor estimates of the functions when the points upon which they are based are close together. On the whole, therefore, the mean profit results (which are averages of "good" and "bad" estimates) are surprisingly good, even those of Run 3. Although, when taken as per cent of maximum profit, the yields of the rules fell considerably in Run 3 (e.g., in that run Rule 3 earned only 55.3 per cent of maximum profit on the average), the absolute discrepancy between maximum profit and mean profit remained substantially unchanged through the three runs, the difference between maximum profits and Rule 3 profits being 417.31 in Run 1, 512.09 in Run 2, and 599.70 in Run 3.

#### *X. Concluding Comments*

The primary goal of this paper has been to open up a new area of investigation rather than to produce any final conclusions. We have discussed the general considerations which must be involved in the choice of effective rules of thumb. The difficulties inherent in the problem, both practical and analytical, were examined in some detail. Because of these problems, and the relative crudeness which characterizes portions of our investigation, even its limited results should, perhaps, be considered rather remarkable. The tests utilized in the analysis seem to have shown themselves capable of producing an effective ranking of alternative rules of thumb.

We are well aware that our results are highly dependent on the nature of the frequency distribution implicit in our random-number generators, on the set of rules which were chosen for testing, and on our methods of construction of the cost and demand functions. Future experimenters

might well try a number of alternatives, including demand and cost data involving random errors of observation and shifting cost and demand functions. The learning rules described in Appendix A would appear to merit further examination, and alternatives to the simulation methods employed in this paper should be considered. Empirical evaluation studies of rules of thumb used in industry might also be undertaken. It is obvious, then, that our main result is a set of suggestions for further research and some degree of assurance that this line of investigation is capable of yielding meaningful conclusions.

There still remains the question, how can the results of such a study be used? Surely, on the basis of our artificial and fragmentary experimentation no serious recommendation can be offered to anyone who is responsible for pricing decisions in practice. One path which may be more promising would require a far larger number and more diversified set of simulation calculations. It might then be possible for any given rule of thumb to characterize the types of situation in which it can be expected to perform relatively well. If this is done with sufficient care and the characterizations are carefully designed to be operational, it may even be possible to apply these conclusions to real decision problems.

At any rate, we have tried to illustrate the surprisingly difficult nature of a problem which, though often mentioned obliquely, seems never before to have been subjected to systematic attack. We must leave it to the reader to judge whether these initial results can be considered encouraging.

#### APPENDIX A: LEARNING RULES OF THUMB

We undertook no simulation study of rules of thumb in which the profit-maker attempts by trial and error to grope his way toward an optimum. Part of the reason is that the simulation model used by us would not have constituted an adequate trial of such a learning rule. With no shifts in the profit function, a well-designed learning rule can usually be relied on to converge toward the optimum as will be illustrated presently. Indeed, experience with analogous mathematical procedures such as Newton's method for approximating the roots of an equation suggests that they will often converge in fairly short order. Only in a model with frequent and unpredictable shifts in the cost and profit function is a learning rule put to the acid test, for only then can we see whether its convergence towards an optimum proceeds more quickly than the obsolescence of the past information which has been used in constructing it. With a fixed-profit function a good learning rule must almost certainly perform more satisfactorily in the long run than any other type of rule of thumb, but whether it will do so in practice depends entirely on the volatility of the relevant functions.

The learning-model pricing procedures can usually be represented by difference equations. However, these equations must be at least of second

order.<sup>16</sup> Such a rule states that the change from the price of this period to the next depends on the preceding price change and the resulting change in profit. Symbolically, we then have  $p_{t+1} - p_t = f(p_t - p_{t-1}, \pi_t - \pi_{t-1})$  where  $p_t$  and  $\pi_t$ , respectively, represent price and profit in period  $t$ , and where we can eliminate the profit figure from the equation by substituting in the profit function,  $\pi = g(p_t)$ .

This difference equation will normally be nonlinear because the profit function is normally nonlinear; indeed, it must be so if (in the absence of constraints) there is to be any profit-maximizing price.

In addition, a nonlinearity will be imparted by the fact that the sign of next period's price change depends both on the sign of last period's price change and on the sign of last period's profit change. More specifically, we require that if profits have gone up, next period's price change will be of the same sign as that of last period. But if profits have fallen, next period's price change will be of sign opposite from that of the preceding period.

One simple relationship which meets this requirement is

$$p_{t+1} - p_t = k \frac{\pi_t - \pi_{t-1}}{p_t - p_{t-1}}$$

if  $p_t \neq p_{t-1}$  and  $p_{t+1} - p_t = 0$  otherwise, where  $k$  is a speed-of-adjustment parameter. But this is only one of many possible equations which will satisfy our learning rule-of-thumb requirements. A simulation approach did not seem necessary since the consequences of such a learning rule can be ascertained analytically in at least some cases, as will now be shown.

(i) *A discrete model with quadratic profit function.* Define  $\Delta p_t$  as  $p_t - p_{t-1}$  and let the profit function be

$$\pi_t = ap_t - bp_t^2$$

where it may reasonably be assumed that  $a \geq 0$  and  $b \geq 0$ . The learning rule then gives

$$\Delta p_{t+1} = k \frac{a(p_{t-1} + \Delta p_t) - b(p_{t-1} + \Delta p_t)^2 - ap_{t-1} + bp_{t-1}^2}{\Delta p_t},$$

which simplifies to

$$(1) \quad p_{t+1} - (1 - b')p_t + b'p_{t-1} = a'$$

<sup>16</sup> A Newton's-method type of learning rule must be of third order. For to find the point of maximum  $\pi$  it seeks a value of  $p$  at which  $\Delta\pi/\Delta p$  approximates zero. This it does by taking two successive values  $(\Delta\pi/\Delta p)_t$  and  $(\Delta\pi/\Delta p)_{t-1}$  and fitting a linear relationship  $(\Delta\pi/\Delta p) = a + b'p$  to these observations. The value of  $p$  which satisfies  $a + b'p = 0$  is the first approximation to the optimal price, and the corresponding marginal profit figure is taken as  $(\Delta\pi/\Delta p)_{t+1}$  for the next iteration. Hence we have a second-order relationship in the  $\Delta\pi/\Delta p$ , which we may write  $(\Delta\pi/\Delta p)_{t+1} = f[(\Delta\pi/\Delta p)_t, (\Delta\pi/\Delta p)_{t-1}]$ . But since  $(\Delta\pi/\Delta p)_t = (\pi_{t+1} - \pi_t)/(p_{t+1} - p_t)$ , this relationship is of third order in our initial variables  $\pi_t$  and  $p_t$ . In other words, each iteration of such a Newton's-method rule requires *three* profit and price observations,  $\pi_{t-1}$ ,  $\pi_t$ ,  $\pi_{t+1}$ ,  $p_{t-1}$ ,  $p_t$  and  $p_{t+1}$ .

where  $b' = kb$  and  $a' = ka$ . It is readily shown that the second-order linear difference equation given by (1) converges to the equilibrium solution  $a/2b$  if and only if  $0 < b' < 1$ . That is to say, the solution converges if (a) the speed of reaction,  $k$ , is sufficiently small or (b) for given value of  $k$ , if the demand function and the marginal cost function are both relatively steeply inclined. For any given value of  $b$  it is then possible to construct a convergent learning rule by selecting  $k < 1/b$ , i.e., by employing a sufficiently moderate speed of reaction.

(ii) *A continuous model.* The learning model can be reformulated as follows:

$$(2) \quad \begin{aligned} \dot{p} &= k \frac{\pi}{p} && \text{if } p \neq 0 \\ \dot{p} &= 0 && \text{otherwise} \end{aligned}$$

where the dot denotes differentiation with respect to time and  $k$  is positive. Equation (2) is the continuous analogue of the discrete model discussed earlier.

Assume now that the profit function is a concave, differentiable function of  $p$ , that is

$$\pi = f(p)$$

and

$$f''(p) < 0.$$

Equation (2) then becomes

$$(3) \quad \dot{p} = k \frac{f'(p)\dot{p}}{\dot{p}} = kf'(p).$$

The stability of (3) is now examined from the global point of view. A system is globally stable if it converges to equilibrium irrespective of the initial condition of the system. Stability can be established by showing that the distance between the solution of (3) and equilibrium declines monotonically with time.<sup>17</sup>

Since equilibrium is given by  $\dot{p}_t = 0$ , we choose as our distance function the Euclidean norm

$$(4) \quad V(t) = \frac{1}{2}(\dot{p} - 0)^2$$

$V(t) \geq 0$  for all  $t$ . If, then, we show that  $\dot{V}(t) < 0$  for all  $t$ , we will have proved global stability.

Differentiating (4) we obtain

$$\dot{V}(t) = k^2 f'(p) f''(p) \dot{p}$$

<sup>17</sup> See Struble [6].

and, since  $kf'(p) = p$ , we have  $\dot{V}(t) = kf''(p)p^2 < 0$  by the concavity of the profit function, and the system is globally stable.

#### APPENDIX B: PROPERTIES OF THE SIMULATED PROFIT FUNCTION

We are fortunate that the distribution of the random variables on which our simulation is based is sufficiently simple to be amenable to direct analysis, and that, on this basis, the performance of Rule 1 can be predicted. For by comparing observed results with those derived from analytic calculations, one can obtain an estimate of the degree of reliability of the simulation approach employed.

Let  $x_i$  and  $y_i$  be random variables distributed uniformly over the integers  $1, \dots, 64$ . The  $x_i$  are the variables which (together) constitute the demand figure, whereas the  $y_i$  add up to the cost figure at any level of price. Let  $t$  be a new variable defined by  $t = 21 - p$  where  $p$  is the price. It is then easy to verify that the method of generating the demand and cost functions yields the profit function:

$$\pi_t = (21 - t) \sum_{i=1}^t (x_i + 2ai) - \sum_{i=0}^t (by_i - 8ci)$$

where the values of  $a$ ,  $b$  and  $c$  in the six runs are as follows:

	Run 1	Run 2	Run 3	Run 4	Run 5	Run 6
$a$	0	0	0	0	0	1
$b$	1	4	8	1	4	1
$c$	0	0	0	1	1	0

Since<sup>18</sup>  $E(x_i) = E(y_i) = 32.5$  and<sup>19</sup>  $\sigma^2(x_i) = \sigma^2(y_i) = 341.25$ , the expected profit and variance can be expressed as

$$E(\pi_t) = (21 - t)(32.5t + at(t + 1)) - b(32.5(t + 1)) - 4ct(t + 1)$$

and

$$\sigma^2(\pi_t) = (21 - t)^2 t \sigma^2(x_i) + b^2(t + 1) \sigma^2(y_i)$$

yielding, for  $p = 11$ , the following figures:

	Run 1	Run 2	Run 3	Run 4	Run 5	Run 6
$E(\pi_t)$	3,217.5	2,145.0	715.0	2,777.5	1,705.0	4,428.0
$\sigma(\pi_t)$	645.4	687.7	808.1	645.4	687.8	645.4
$\sigma(\bar{\pi}_t)$	132.0	140.6	165.3	132.0	140.6	132.0

<sup>18</sup>  $E(x_i) = E(y_i) = \frac{1}{64} \sum_{i=1}^{64} i = 32.5$ .

<sup>19</sup>  $\sigma^2(x_i) = \sigma^2(y_i) = \frac{1}{64} \sum_{i=1}^{64} (i - 32.5)^2 = 341.25$ .

The observed mean profit under Rule 1 approximates well the theoretical mean in all runs, although all observed means are greater than the corresponding theoretical quantities. The observed standard deviations tend to be lower than the theoretical ones but, using the test quantity  $ns^2/\sigma^2$  distributed as  $\chi^2$ , we cannot reject the hypothesis on the .10 significance level that the observed distributions are generated by theoretical distributions with the stated means and standard deviations. Whatever relatively bad agreement exists between some of the observed and theoretical quantities must be attributed to the random-number generator.

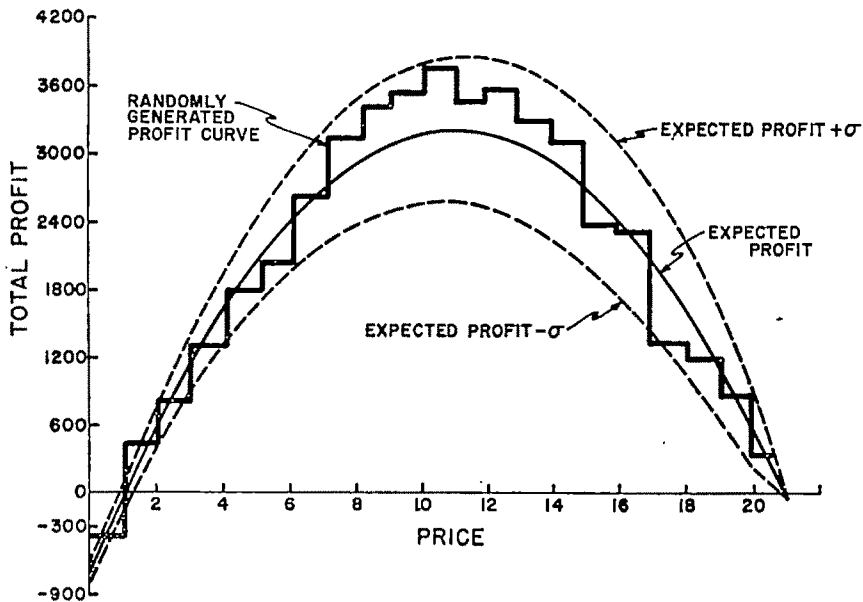

FIGURE 1

The relative goodness of Rule 1, particularly in Runs 1 and 6, becomes understandable in view of the fact that the expected profit function is fairly flat in the neighborhood of  $p=11$ : for example, for a price of \$14 expected profit diminishes in Run 1 from 3217.5 to 2925.0, less than 10 per cent. The situation can be made clearer with the aid of a graph. Figure 1 represents our simulated profit function. For Run 1 the expected profit function is a parabola with its maximum at  $p=11$ . If we draw dotted curves one standard deviation above and below the expected profit curve, we obtain a band between these lines that is rather narrow near the tails of the parabola but widens considerably in the neighborhood of the maximum point. This means that the simulated profit figures almost certainly must rise just to the right of the origin and that they almost certainly must fall as the expected profit graph approaches the horizontal axis. However, in the middle range, the stochastic curve can be relatively flat. This means that even when the peak of the expected profit curve is shifted to the right (as

it was in Runs 2 and 3) a fixed price  $p=11$  may still yield a total profit figure very close to the maximum profit level. It also becomes clear why Rule 1 does not do so well in Runs 2 and 3: the expected profit functions corresponding to these runs achieve their maxima at higher and higher prices. As a matter of fact, the observed mean optimal price was 10.25 in Run 1, 13.42 in Run 2, 14.58 in Run 3, 13.00 in Run 4, 13.83 in Run 5, and 10.88 in Run 6.

## EXPORT CONCENTRATION AND FLUCTUATIONS IN EXPORT EARNINGS: A CROSS-SECTION ANALYSIS

By BENTON F. MASSELL\*

In recent years there has been considerable discussion of the problem of fluctuations in commodity markets and the impact of these fluctuations on countries producing primary products. The newly developing countries, in particular, many of whom are heavily dependent upon earnings from the sale of primary commodities to finance much-needed capital goods imports, have evidenced substantial concern with the instability of their export proceeds. In large part, this concern derives from the fact that commodity prices—and, consequently, foreign exchange earnings—have often exhibited a tendency towards secular decline; but in part it stems also from the shorter-run fluctuations around the trend.<sup>1</sup>

To a considerable extent, the source of fluctuations in export proceeds—at least, from the standpoint of a single country—is often believed to be concentration on an unnecessarily narrow range of products for export. There are many examples of so-called “one crop economies,” such as Ghana (cocoa), Mauritius (sugar), and Sudan (cotton). It is sometimes argued that if these economies were to diversify their exports, their export earnings would exhibit a greater degree of stability over time.<sup>2,3</sup>

In the present study an attempt is made to determine whether diversification is likely to provide a greatly increased measure of stability in export earnings.<sup>4</sup> This is done by examining empirically, in a sample of

\* The author is a research economist at The RAND Corporation. This research is sponsored by the United States Air Force under Project RAND. Views or conclusions contained in this article should not be interpreted as representing the official opinion or policy of the United States Air Force. The author is indebted to RAND colleagues R. C. Kao, A. W. Marshall, and E. Neuberger for a number of helpful comments and suggestions.

<sup>1</sup> Given the prices paid for imports, the trend in export proceeds determines the long-run gains that accrue to a country from international trade, and hence is an important determinant of the secular rise in the country's material welfare. Nevertheless, whatever the trend in export earnings may be, there are obvious advantages in reducing fluctuations around this trend. Uncertainty and unreliability of annual foreign exchange earnings may well create complexities in development planning. Furthermore, fluctuations in exchange proceeds tend periodically to exert strains on the balance of payments, possibly resulting alternatively in inflationary and deflationary pressures on the economy.

<sup>2</sup> “Fluctuations in proceeds from particular exports are more serious if the country concerned cannot rely on an averaging of the price movements of many different types of goods” [6, p. 9].

<sup>3</sup> The United Nations has noted, “A high degree of specialization is often a result of small ‘economic size,’ and is accompanied by a high degree of dependence on foreign trade, so that fluctuations in export proceeds have a devastating effect on the domestic economy” [6, p. 10].

<sup>4</sup> Two recent publications which deal with related issues are Michael Michaely's book [3]

36 countries, the extent to which fluctuations in a country's export earnings tend to be associated with concentration of the country's exports. A linear regression model is used which expresses export instability, the dependent variable, as a function of several independent variables. Section I considers the definition and measurement of an index of instability, while Section II develops an index of concentration. The empirical results are presented in Section III, and some conclusions, suggested by these results, in Section IV.

It is worth noting that a statistical study such as the present one has certain limitations. Aside from the usual qualifications which necessarily attach to the conclusions of any study based on regression analysis, there is a further qualification which stems from the uniqueness of countries and of commodities—or, more precisely, from the uniqueness of the particular choice confronting any country. Whatever the observable statistical relationship between concentration and instability in a cross-section of countries, a single country may rightly feel that its own position is sufficiently atypical to make these results of little interest. Thus, Ghana's decision whether or not to produce coffee in addition to cocoa should be based on the relationship between coffee and cocoa prices (among other things), rather than on generalizations based on aggregates of countries and of commodities.

Nevertheless, there is reason to believe that the conclusions presented in the following pages may provide general guidelines of some use in development planning by yielding a better understanding of certain fundamental economic relationships. Moreover, if the results cannot be given prescriptive value, perhaps they can at least explain existing intercountry disparities.

### *I. The Measurement of Export Receipt Instability*

The observable changes over time in the value of exports result from the interaction of a variety of market forces, both on the supply and the demand sides. It is an arbitrary, but nevertheless convenient, procedure to distinguish between long-run forces, which can be said to determine the trend, and short-run forces, which can be viewed as determining fluctuations around the trend.<sup>5</sup> If a measure of instability is used which does not distinguish between the two sets of forces, then a country with a rapid secular increase (or decrease) in its export earnings will exhibit

---

and Joseph D. Coppock's book [1]. Unfortunately, the present study was essentially completed before I had access to either of these works. However, at the end of Section III the relationship between these two works and the present one is briefly discussed.

<sup>5</sup> It should be noted that intra-year fluctuations, which are appreciable in some cases, are not considered in this study.

greater instability than a country whose export earnings are secularly unchanging. For our purposes, this result would be undesirable. It appears more appropriate to measure annual fluctuations not around the mean but around the trend.

One way to do this is to fit a regression line to export earnings expressed as a function of time, and then measure exports as deviations from this estimated trend. Thus, we can write:

$$(1) \quad Z_t = \beta_0 + \beta_1 t,$$

where  $Z$  = export earnings,  $t$  = time, and where the  $\beta$ 's can be estimated by least squares.<sup>6</sup>

Using equation (1), the linear time trend was estimated for each of the 36 countries in our sample for the period 1948-59, with  $Z$  defined as the money value (in current monetary units) of the earnings received by the country from the sale of all merchandise exports.<sup>7</sup> The trend coefficients,  $\beta_1$ , together with the respective correlation coefficients,  $r$ , are presented in Table 1. The  $\beta_1$ 's range from .159 for Japan to -.019 for Argentina, the only country in the sample with a negative rate of growth for the period.<sup>8</sup>

As an index of instability, two measures, both trend-corrected, appear equally satisfactory. One is the standard error of estimate (square root of the unexplained variance), divided by the mean of the observations. This measure, which we shall term the "normalized standard error," is a pure number and is thus independent of the over-all level, or of the rate of growth, of a country's exports. We can write this variable:

$$(2) \quad I = \frac{\sqrt{\frac{\sum(u_i)^2}{n}}}{\bar{Z}}$$

where  $u_i = Z_t - (\beta_0 + \beta_1 t)$ ,  $n$  = the number of years in the series, and  $\bar{Z} = \sum Z_t / n$ .

Alternatively, we can use the average annual percentage rate of change in the value of exports, also trend-corrected, as given by:<sup>9</sup>

<sup>6</sup> In using equation (1) it is assumed that the trend can most appropriately be approximated by a linear function of time. In fact, an exponential trend was also fitted to the data, but inspection of the residuals suggested that the linear trend provided a better fit.

<sup>7</sup> In this estimate 1948 was chosen as the initial year in the belief that it represented the first "normal" postwar year. All the data used in this study were obtained from United Nations [8].

<sup>8</sup> In fact, the UAR also had a negative rate of growth, but this rounded off to zero for three decimal places.

<sup>9</sup>  $I^*$  is also a pure number.

$$(3) \quad I^* = \frac{\sum w_i}{n},$$

where

$$(4) \quad w_i = \frac{|u_{i+1} - u_i|}{\max. [Z_i, Z_{i+1}]}.$$

In the subsequent analysis we shall use both measures.

The variables  $I$  and  $I^*$  were computed for each country and are

presented in Table 2, columns 2 and 3, respectively. With the exception of Malaya ( $I = .284$ ), the values of  $I$  are relatively uniformly distributed between .057 (Canada) and .184 (Colombia). There seems to be a tendency for the countries commonly regarded as "underdeveloped" to have a larger value of  $I$  than the more economically advanced nations, although it is noteworthy that some underdeveloped countries have quite low values of  $I$ —for example, Trinidad (.060) and Panama (.082).

Turning to  $I^*$ , the values range from .051 (United Kingdom) to .202

(Malaya). For most countries, the value of  $I^*$  corresponds rather closely to that of  $I$ , but there are notable exceptions to this, for example, Malaya and Colombia. Spearman's Rank Correlation Coefficient was computed to test the significance of the country rankings according to the two indexes and was found to equal .718, with standard error .17, which is significant at the .01 level. The two measures of export instability are, of course, conceptually quite distinct; where  $I^*$  is a measure more of year-to-year changes,  $I$  is a measure of the variation of the series as a whole around the trend line. Either measure is influenced by the appropriateness, for a particular country, of fitting a linear time trend, but a poor fit would affect  $I$  more than  $I^*$ .

## II. A Measure of Export Concentration

One measure of export concentration, recently used by Michael Michaely [4], is the Gini coefficient, written

$$(5) \quad C = \sqrt{\sum (x_i/x)^2}$$

where  $x_i$  = the value of exports of commodity  $i$  in some specified year,<sup>10</sup> and  $x = \sum x_i$ . If a country that produces a given number of products for export divides its resources more evenly among these products, this will result in a reduction in  $C$ .  $C$  will also be reduced if the country produces an *additional* product for export provided that:<sup>11</sup>

$$(6) \quad 0 < \sum_{i=1}^m d_i \leq p'_i \leq p_i \leq 1, \text{ all } i,$$

where  $p_i$  = the proportion of the economy's resources initially devoted to the production for export of commodity  $i$ ,  $p'_i$  = the proportion after a new commodity has been added, and  $d_i = p_i - p'_i$ .

As Michaely has pointed out, the value of  $C$  depends in an important way on what commodity-classification scheme is employed. In particular,  $C$  will be higher, the greater the level of aggregation over commodities, for at a higher level of aggregation products which are relatively dissimilar are classified together. Thus, a country, all of whose exports fall within a single large group but are highly diversified within this group, may have a value of  $C$  higher than that of another country which is virtually a one-crop economy, but which produces also some product in a different group. A corresponding problem obviously arises if a highly disaggregated classificatory scheme is used. We have chosen, consequently, to compute  $C$  for the 36 countries in the sample on the

<sup>10</sup> In most cases, 1959 data were used in this study; where 1959 data were unavailable or incomplete, 1958 data were used.

<sup>11</sup> For a more detailed discussion of this point, see my forthcoming paper, "A Note on Export Diversification."

United States	.160	.431	.337	.292

<sup>a</sup>  $P$  is a measure of a country's concentration on primary products.

<sup>b</sup>  $G$  is a measure of a country's geographical concentration of exports.

basis of two classification schemes, differing in the level of aggregation involved: (1) on the basis of the Standard International Trade Classification (SITC) one-digit industries, and (2) on the basis of the SITC three-digit industries—denoted  $C_1$  and  $C_2$ , respectively.<sup>12</sup>

We computed both measures of concentration for the group of 36 countries. The values of  $C_2$  appear in Table 3, column 2. These values

<sup>12</sup> Another problem is the appropriateness of the SITC commodity breakdown to the analysis presented here. For example, if industrial products are classified more finely than agricultural commodities, primary-product exporting countries will be biased towards greater concentration.

<sup>a</sup>  $G$  is a measure of a country's geographical concentration of exports.

<sup>b</sup> Michaely's figures include Singapore.

Sources: Massell, Table 3; Michaely [4].

range all the way from .160 (United States) to .991 (Mauritius). With few exceptions, the less-developed countries tend to have higher values of  $C_3$ , as one would expect.

For comparison we present in Table 4, together with our own values of  $C_3$ , those obtained by Michaely for many of the same countries, based on 1954 exports.<sup>13</sup> As one can see, Michaely's figures tend to correspond fairly well with ours, although he obtains higher values of  $C_3$  for 19 of the 28 countries compared. The difference between the two sets of figures may be due to any of three factors: (1) To some extent, the structure of exports of several of the countries may have altered in the interval 1954 to 1959. (2) The country's methods of reporting the data, while supposedly standardized, may have been changed during this

<sup>13</sup> Michaely [4] computed  $C$  for the SITC three-digit classification only.

interval; for example, reporting exports in greater detail in more recent years would tend to make our  $C_3$  lower than Michaely's. (3) Perhaps, also, differences in processing the published data may have accounted for some of the discrepancy.

In column 3 of Table 3 are shown the values of  $C_1$ . One can see that, from the definition of the  $C$  indexes, the following inequality must hold for any country:

$$(7) \quad C_1 \geq C_3.$$

$C_1$  tends to be appreciably larger than  $C_3$ , reflecting the difference in aggregation.  $C_1$  ranges from .420 (Netherlands) to 1.000 (Mauritius).

### III. *Empirical Results*

To estimate the relationship between the instability and concentration of exports, regression analysis was used, with  $I$  and  $I^*$ , alternatively, as dependent variables, and  $C_1$  and  $C_3$  as independent variables. The regression equations are written:

$$(8) \quad I = a_{i0} + a_{i1}C_i$$

$$(9) \quad I^* = a_{i0}^* + a_{i1}^*C_i$$

where  $i=1, 3$ .

The entire sample of 36 countries was used to estimate the coefficients in (9), but for (8) Malaya was deleted, as the value of  $I$  for this country was sufficiently greater than the next highest value to suggest that it might represent a special case which it was safer to omit.<sup>14</sup>

The estimated regression coefficients for  $C_1$  and  $C_3$  are presented in Table 5, with the standard errors in parentheses beneath their respective coefficients. With a one-tailed test, none of the slope coefficients is significant at the .05 level.

Before concluding that the insignificance of the simple regressions implies the rejection of the hypothesized relationship, let us add an additional variable to the model. We begin by noting that concentration can refer not only to the commodity composition of a country's exports but also to the geographical composition of established markets for these products. A country whose exports were destined principally for only one or two countries would be termed highly concentrated in the latter sense; diversification would involve seeking a greater variety of markets or spreading exports more evenly over existing markets.

To measure the geographical concentration of exports, we turn again to the Gini coefficient, as given by

$$(10) \quad G = \sum (Y_i/Y)^2$$

<sup>14</sup> See Table 2 for the range of values of  $I$ .

TABLE 5—RELATIONSHIP BETWEEN EXPORT INSTABILITY AND CONCENTRATION

Equation number in the text	Dependent Variable	Independent Variables: Regression Coefficients (standard errors in parentheses)				Coefficient of Determination <sup>a</sup> $R^2$	$F$ -ratio <sup>b</sup>
		$C_0$	$C_1$	$P$	$G$		
(8)	I	.037 (.032)				.090	3.26
(8)	I		.043 (.032)			.046	1.59
(11)	I	.055 (.027)			-.043 (.033)	.117	2.12
(11)	I		.073 (.041)		-.046 (.036)	.093	1.64
(13)	I			.052 (.019)	-.056 (.032)	.201	4.03
(9)	I*	.060 (.041)				.033	1.16
(9)	I*		.068 (.042)			.038	1.35
(12)	I*	.046 (.027)			-.053 (.034)	.100	1.82
(12)	I*		.056 (.038)		-.046 (.033)	.078	1.35
(14)	I*			.048 (.019)	-.067 (.033)	.172	3.42

<sup>a</sup> The coefficient of determination is the proportion of the total variance of the dependent variable which is "explained" by the regression.

<sup>b</sup> The  $F$  ratio is given by:  $F = R^2(n-k-1)/(1-R^2)k$ , where  $n$  is the number of observations in the sample and  $k$  is the number of independent variables. The only values of  $F$  significant at the .95 level are those for equations (13) and (14).

where  $Y_i$  = exports to country  $i$ , and  $Y = \sum Y_i$ . The values of  $G$  for the 36 countries appear in Table 3, column 5. These values range from .212 (United Kingdom) to .967 (Panama). In Table 4, above, the values of  $G$  are compared with those obtained by Michaely [4].<sup>15</sup> For 10 of the 28 countries compared, Michaely arrives at a higher value of  $G$ .

One could argue that, if geographical concentration indicates the absence of flexibility, then this variable might be expected to be positively correlated with instability. On the other hand, it is quite possible that countries whose exports are highly concentrated geographically

<sup>15</sup> The measure  $G$  was also computed by Albert Hirschman [2].

tend to have more effective methods of smoothing out the fluctuations in export receipts, perhaps because bilateral commodity arrangements may be more prevalent in such cases. Those countries in the sample with high values of  $G$  tend to ship a major part of their exports to the United States or the United Kingdom. In many cases, it is likely that some form of commodity agreement between the exporting and importing countries tends to reduce fluctuations in export receipts. Perhaps the dominant trading partner in these cases either pegs the price of the staple exports or else imports a guaranteed amount, in either case insulating the exporter from the full impact of market forces.

By adding the new variable, the regression equations can be rewritten:

$$(11) \quad I = \gamma_{i0} + \gamma_{i1}C_1 + \gamma_{i2}G,$$

and

$$(12) \quad I^* = \gamma_{i0}^* + \gamma_{i1}^*C_1 + \gamma_{i2}^*G.$$

The estimated regression coefficients are presented in Table 5.

Turning first to the regressions on  $I$ , we see that both  $\gamma_{i1}$  and  $\gamma_{i2}$  are significant at the .05 level, with a one-tailed test. Further, the  $\gamma_{i0}$ , though insignificant at the .05 level with a two-tailed test, are both negative. Thus, the results suggest that  $I$ , while not simply correlated with either  $C_1$  or  $C_2$ , is correlated with each of these two variables *net* of geographical concentration. In other words, given the degree of geographical concentration of a country's exports, the instability of its export receipts is positively correlated with commodity concentration. As indicated in Table 5 by the  $F$ -ratio<sup>18</sup> (or by the value of the coefficient of determination,  $R^2$ ), a greater proportion of the intercountry variation in  $I$  is explained by employing  $C_2$  and  $G$ , rather than  $C_1$  and  $G$ , as the pair of independent variables, although even with the former pair nearly 90 per cent of the variation remains unexplained. The partial correlation coefficient between  $I$  and  $C_2$  is .338, while that between  $I$  and  $C_1$  is .300.

With  $I^*$  as the dependent variable, Table 5 shows results similar to those just discussed. However, the only significant regression coefficient is  $\gamma_{i2}^*$ , and the  $\gamma^*$ 's are slightly lower in value than the  $\gamma$ 's. The  $F$ -ratio is also lower, suggesting that the independent variables provide a better explanation of intercountry variation in  $I$  than in  $I^*$ .

The low correlation between instability and concentration seems to contradict established doctrine, and thus merits further attention. To some extent, the low correlation may result from large differences in the volatility of different commodities. Some products—notably primary

<sup>18</sup> Neither value of  $F$  is significant at the .95 level.

products—are subject to large shifts in the demand schedule because of changes in expectation or because of the cyclical character of industrial activity in the more mature economies, while other products have a relatively stable demand pattern. Moreover, products differ in the extent to which they are subject to fluctuations on the supply side—for example, some primary products are affected by the weather or by the incidence of various types of plant disease. The over-all result is that the extent of fluctuations in price and in volume traded—and in the product of the two—differs markedly from one product to another. In the context of the present inquiry, this means that the countries that specialize in the more volatile products will tend to show a more marked instability of export revenues, for a given concentration of exports, than economies whose exports consist primarily of the more stable products. But, to the extent that one would expect a systematic relationship between concentration of exports and volatility of the goods exported, this relationship should strengthen the positive correlation between instability and concentration. Primary products can be expected to be more volatile than manufactured goods, and the exports of primary producing countries are typically more highly concentrated than those of industrial economies.<sup>17</sup> However, if the disparity in the instability of earnings from the sale of different products is sufficiently great, then, while the regression line will have a positive slope, there will nevertheless be considerable scatter around the line—and this is in fact what has been observed.

Another point, though, should be considered. The rationale for diversification is based on the assumption of statistical independence between annual changes in earnings from the export of any two products. But if the cross elasticity of demand for two commodities is high, then a shift in the demand for one is likely to be accompanied by a comparable shift in demand for the other, and the proceeds from the two products will tend to be intercorrelated. If the intercorrelation is sufficiently great, the value of diversification will be greatly reduced. Of course, shifts in the demand schedule account for only part of the fluctuations in export earnings; another part is due to shifts in the supply curve, and there is less reason to expect a high degree of correlation between the supply schedules of different products.<sup>18</sup> Thus one can expect some random element to be present in the determination of export earnings from the production of different commodities.

While we cannot investigate here the statistical independence among products, it is of some interest to examine briefly the price changes for a selected group of commodities for the period 1950–58, shown in

<sup>17</sup> See below; also, cf. Michaely [4].

<sup>18</sup> Although a drought will result in reduced production of most agricultural commodities.

TABLE 6—EXAMPLES OF FLUCTUATIONS IN COMMODITY PRICE INDEXES

Commodity	Price Index (January-June 1950 = 100)

<sup>a</sup> High for period.

<sup>b</sup> Low for period.

Source: United Nations [7 p. 181].

Table 6. We see that four commodities reached a high in 1951, three in 1954, one each in 1955 and 1959, and one both in 1953 and in 1955; while two reached lows in 1950, one each in 1953 and 1954, two in 1956, and four in 1958. While there is apparently some intercorrelation among the time paths, this intercorrelation is far from perfect.

Nevertheless, there may be some merit in examining an alternative hypothesis: that fluctuations in export earnings result not from high export concentration, as defined by the Gini coefficient, but from concentration on the export of primary products, as opposed to industrial goods. This might be the case if intercorrelation between the earnings time paths of two primary products tends to exceed that between the earnings time paths of two industrial goods, or of an industrial good and a primary product, perhaps because of a similarity in the market forces affecting many internationally traded primary products.

To measure the extent of a country's concentration on primary products, we have used the ratio,  $P$ , of primary-product exports to total exports, where primary products were defined as SITC Groups 0 to 4. This variable, which we shall term the primary-product ratio, was computed for the sample of countries and is shown in column 4 of Table 3. The values range from .120 for Japan to 1.000 for several countries.

The regression equations can now be written:

$$(13) \quad I = \xi_0 + \xi_p P + \xi_g G$$

and

$$(14) \quad I^* = \xi_0^* + \xi_p^* P + \xi_g^* G.$$

The coefficients appear in Table 5.

Using a one-tailed test, one finds a significant correlation at the .05 level between either  $I$  or  $I^*$  and  $P$ , net of  $G$ .<sup>19</sup> An increase in  $P$  by 20 percentage points, given the value of  $G$ , is associated with a 1 per cent rise in either  $I$  or  $I^*$ , indicating that  $P$  explains only a small part of the variation among countries in export instability. As indicated by the  $F$ -ratio, the pair of variables,  $P$  and  $G$ , provide a better explanation of variation in  $I$  than in  $I^*$ .

The partial correlation coefficient between  $I$  and  $P$ , in equation (13), is .445 compared with a value of .338 between  $I$  and  $C_3$  in equation (11). This suggests that  $P$  provides a better explanation than  $C_3$  (which, in turn, is better than  $C_1$ ) of the variation in  $I$ . The  $F$ -ratios confirm that the pair of variables,  $P$  and  $G$ , provides the best explanation of inter-country variation in either  $I$  or  $I^*$ . In both cases,  $F$  is significant at the .95 level.

An attempt to include both  $P$  and either  $C_3$  or  $C_1$  as independent variables yielded no significant results, possibly because of multicollinearity. In fact, it can be observed that  $C_3$ ,  $C_1$ , and  $P$  all appear to be intercorrelated, thus indicating that primary-producing countries tend to have more highly concentrated exports.

While the low correlation between  $I$  and either  $C$  index is not at all what one would expect, the weak relationship between  $I$  and  $P$  is, perhaps, even more surprising. These results suggest that we must reject the view that fluctuations in export earnings affect only the primary-producing countries; apparently the industrial countries share this instability in nearly the same measure. One should note, though, that some commodities are now subject to control, so that the statistical results reflect, in part, these institutional arrangements. The low degree of correlation between  $I$  and any of the independent variables must not be interpreted as suggesting that the commodity stabilization schemes now in effect are gratuitous; indeed, it may be that the partial success of these schemes has contributed to the low observed correlations. Fluctuations in the export earnings of primary-producing countries might have been considerably worse in the absence of these commodity control arrangements.<sup>20</sup>

It is of some interest to discuss briefly the relationship between this study and those of Coppock [1] and Michaely [3]. Coppock's book is broader in scope than the present study, as his title suggests. However, his Chapters 5 and 6 are concerned with explaining the instability of export proceeds, as is the present work. Included in the nearly 40 independent variables which Coppock considers are both commodity con-

<sup>19</sup> With  $I$  as dependent variable,  $G$  is also significantly negative at the .05 level, using a two-tailed test. A simple regression of  $I$  or  $I^*$  against either  $P$  or  $G$  fails, however, to be significant.

<sup>20</sup> This is particularly so if—as seems likely—the most volatile commodities are the ones which have been made subject to international agreements.

centration and geographical concentration of exports (although not the primary-product ratio). Although Coppock's multiple correlation results are not comparable with ours, due to fundamental differences in methodology, it is interesting to note that he finds neither commodity nor geographical concentration important in a simple regression.

We referred earlier to the relationship between our measures of concentration and those of Michaely. Here we shall consider briefly the relationship between Michaely's Chapter 5 ("Commodity Concentration and Price Fluctuations") and the present study. In his Chapter 5, Michaely constructs an index of export *prices* for the countries in his sample. He finds that fluctuations in this index are positively correlated with concentration of the country's exports and with the primary-product ratio, taking each independent variable separately; the respective correlation coefficients are .397 and .252. However, on the basis of partial correlation analysis, Michaely concludes that the simple relationship between export instability and the primary-product ratio is "solely due to the strong association between commodity concentration and the extent of specialization in primary goods" [3, p. 78]. Michaely also looks at the relationship between fluctuations in export *volume* and concentration of exports, and finds a positive rank correlation.

Our results above indicate a positive (but insignificant) simple correlation between export *proceeds* and concentration. For example, from Table 5 we see that the simple correlation coefficient for equation (8) is .3. But, because Michaely uses *rank* correlation for part of his study, and because he does not consider the statistical significance of many of his coefficients, it is difficult to say to what extent his results are consistent with ours.

#### IV. Conclusions

Several points appear to follow from the preceding analysis. First, it is clear that the relationship between instability of export earnings and concentration of exports is a tenuous one indeed.<sup>21</sup> As the degree of concentration of a country's exports explains such a small proportion of the intercountry variation in export instability, one would not expect a policy aimed at diversification generally to result in a marked reduction in fluctuations—although such a policy may well be effective in certain individual cases.

As the relationship between instability and the primary-product ratio is also relatively weak, this investigation gives little support for in-

<sup>21</sup> Moreover, the results suggest that the observed relationship between instability and concentration may result from (1) the relationship between instability and the primary-product ratio, together with (2) the tendency for primary-producing countries to have highly concentrated exports.

dustrialization as a method of reducing export instability. But the fact that neither diversification nor the degree of industrialization appears to explain much of the variation in export instability has other implications. Why, one might ask, do the primary-producing countries typically exhibit so much concern with the problem of instability if, as the data indicate, the industrialized countries have been subject to export fluctuations to nearly the same extent? One reason may be that primary-producing countries tend also to be low-income countries and are consequently more disturbed by fluctuations than wealthier countries. Also, primary-producing countries tend to depend more heavily on exports as a source of income than do industrialized countries, so that a given degree of export instability has a greater impact on the economy of a primary-producing country.

Furthermore, fluctuations in commodity prices may have a real cost to primary producers quite apart from the visible effect on annual earnings. To some extent, perhaps, the producers have responded to price changes by means of offsetting changes in volume offered for sale [5]. Thus a rise in price may have been met by a fall in volume, and a fall in price by an increase in volume. We shall not examine here whether this seems to be the case, but will merely note that, in instances where this may have occurred, the primary-producing countries have achieved greater revenue stability, but at a cost. However, diversification would presumably not reduce this cost for the individual producer.

We conclude by noting that it is unlikely that either instability of export earnings or the disutility arising from such instability will be eliminated by simple policies, such as producing a wider range of exports. To the extent that the disutility created by fluctuations in exports is intensified by the low incomes of the primary-producing countries, the problem is basically a manifestation of poverty and, as such, will be eliminated or reduced as the country achieves economic development.

The general case for diversification (or, indeed, for industrialization) as a cure for fluctuations in export earnings receives little support from this investigation. For a given country, however, there may be some gain in choosing a *particular product* that will help reduce the fluctuations in its exports receipts. And of course diversification may be beneficial in other ways, for example, in providing the economy with greater flexibility in adapting the structure of its production to changes in market conditions.

## OPTIMIZATION AND SUBOPTIMIZATION IN FISHERY REGULATION

By RALPH TURVEY\*

The purpose of this article is to show that fishery regulation is one of those spheres of economic policy where what is the best thing to do depends on what can be done. This is usually illustrated by the analogy that, if one wants to climb as high as possible but cannot climb all the way up the highest mountain, the best thing to do may be to walk in the opposite direction and climb to the top of a lower one. If the *optimum optimorum* is to be reached (the highest mountain scaled), then regulation must extend not only to the scale but also to the mode of operation.

That this rather general point has an important application in fisheries management became apparent to me during a conference in Ottawa of economists, biologists, and administrators organized by the Food and Agricultural Organization in 1961. The proceedings of this conference have now been published [8]. The two general survey papers by Professor Scott and Dr. Dickie at the beginning of this volume afford an admirable survey of the whole subject, including a review of the literature. I shall therefore not attempt to summarize their contributions, and what follows is a self-contained argument which may, however, incidentally serve to introduce readers to a fascinating subject where economists and biologists are clearly complements and only talk as though they were substitutes when they misunderstand one another.

What follows is a static (i.e., steady state) analysis of a single-trawl fishery where there is only one fish stock, fished from ports which supply a common market and which are equidistant from the fishing ground. It is assumed that the port market is competitive and that there are no restrictions on entry into the fishery. These assumptions serve to make the exposition reasonably simple; their removal would not destroy the essential argument of the paper.

\* The author is reader in economics at the London School of Economics. He is much indebted to R. J. H. Beverton, L. M. Dickie, B. B. Parrish, F. A. Popper, and A. D. Scott for their constructive comments on an earlier draft of this paper.

### I. *Catch*

The determinants of the weight of catch, under these assumptions, are twofold,<sup>1</sup> given constant natural population parameters. The first is the rate of capture (the fishing mortality rate) of the fish liable to capture, which is proportionate to the amount of fishing effort. This is defined as the product of the number of hours' fishing (or some other index of fishing time) and of fishing power, where the fishing power of any particular ship is defined by reference to a standard vessel by comparing their catches when fishing at the same time and place. In practice, the fishing power of trawlers is broadly related to the gross tonnages, so that fishing effort in a given time interval may be measured as the average gross tonnage of the fishing fleet multiplied by the total number of hours' fishing. The relevance of fishing effort is simply that, if it is decreased, the stock of fish will grow and the average age, weight, and size of the fish will increase, making fishing easier, i.e., increasing catch per unit of fishing effort.

The second determinant of the weight of catch is the size (age) at which the fish become liable to capture, i.e., are "recruited" to the fishery. In a trawl fishery, which is the example we take here, this is regulated by the mesh size of the cod-ends of the trawls used. This determines the minimum size of fish caught; the larger the mesh, the older, larger, and heavier will be the fish liable to capture. Thus, other things remaining the same, an increase in mesh size will initially reduce the catch but may ultimately raise it by increasing the stock. Here, since the analysis is static, it is only this ultimate effect which concerns us.

Biologists have formulated a number of models which provide a function relating the weight of catch to the two variables, mesh size and fishing effort. These models deal with the rates of natural mortality, growth, and recruitment, each of which is a function of the size of the stock and its age distribution. As in economics, metrics is several steps behind theory, however, so that not all the parameters of the more complicated models can at present be estimated, owing to lack of data. Things which are known to be relevant, such as the spatial distribution of fishing effort, just have to be ignored. If we confine ourselves to the operational models used for most fishery assessments, the simplified biological interrelationships that have been introduced are the following: (a) natural mortality a function of age; (b) growth of the fish, by weight and length, a function of its age; (c) recruitment to the fish stock, i.e., the number of fish reaching catchable size, treated as exogenous; and (d) fishing mortality rate proportional to fishing effort.

<sup>1</sup> The standard work on all this is by R. J. H. Beverton and S. J. Holt [1]. On the measurement of "fishing effort" see also J. A. Gulland [3]. A useful survey article, of which Dr. Parrish has kindly lent me a translation, is by G. Hempel and D. Sahrhage [4].

The steady-state catch in weight from a fish stock is then determined by the interaction between the rates of these natural processes and the fishing mortality rate. The relationship between weight of catch and age of recruitment (mesh size) and fishing mortality rate (fishing effort), estimated from a simple, dynamic model in which the rates of the natural processes are assumed constant, takes the form shown in Figure 1, where fishing effort is measured horizontally and weight of catch is measured vertically. Each yield curve shows catch as a function of fishing effort for a given age of recruitment to the fished stock. (The dotted line will be explained later.)

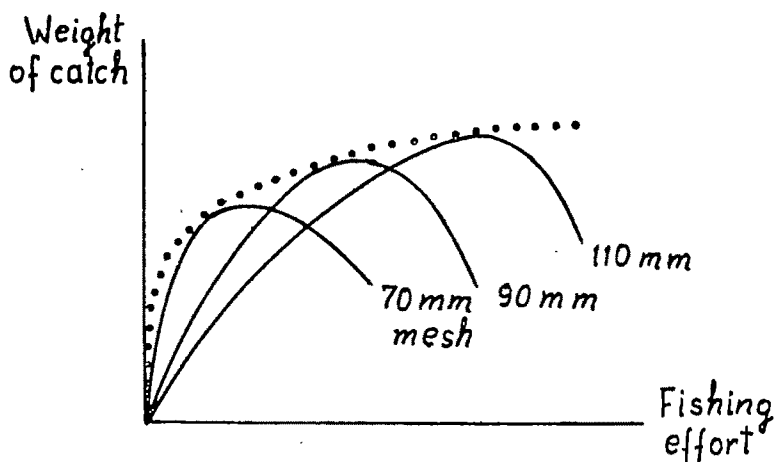

FIGURE 1

## II. Costs

The study of fishing costs is a complicated matter. To illustrate, a large part of fishermen's remuneration is a share in profits rather than a wage.<sup>2</sup> Such matters are not relevant to the argument of the present paper, however, so I shall exclude them by simply assuming that over the relevant range of catch, the total cost of fishing effort rises more than proportionately to the amount of fishing effort because the minimum earnings necessary to attract and retain labor and capital at the margin rise as more of these resources are employed in fishing. Total cost is defined to include the "rents" of the intramarginal factors, i.e., the excess of their actual earnings over the minimum required to retain them in the industry. This is the only aspect of costs that we require in the present argument, so I need not discuss whether few ships fish

<sup>2</sup> See Zoutewij, "Fishermen's Remuneration" in [7]. Economies of scale in shore installations constitute another example.

many hours or vice versa, since fishing effort as defined above is the independent variable of the cost function. What is significant in this formulation is the implicit assumption that mesh size has no noticeable effect upon the costs of fishing effort. This is probably true within the range of mesh size that is relevant in practice.

### III. *Revenue*

The price of fish, given income levels and the prices of other foods, depends not only upon the total weight of the catch but also upon its size distribution and upon its freshness. Here we shall assume that there is some given minimum marketable size of fish; otherwise I neglect these points.<sup>3</sup> Thus I postulate a given function relating total revenue to weight of catch.

### IV. *Steady-State Bionomic Equilibrium*

Let us postulate that: (1) any fluctuations in the natural processes are small and have no trend; and (2) there is free entry of resources to the fishery. Then, given all the various functions discussed above, the long-run equilibrium position can be deduced.

On the economic side, the equilibrium condition is that total revenue equals total cost including the rent of intramarginal factors. We put it this way rather than in terms of average revenue and long-run marginal cost because average revenue is related to weight of catch and marginal cost to fishing effort. In order to relate average revenue to marginal cost, we would have to convert catch into effort, and write the condition as:

$$\text{Price} \times \text{Catch per unit effort} = \text{Marginal cost of fishing effort excluding rent}$$

$$\text{i.e., Average revenue} \times \text{Catch per unit effort} = \text{Average cost including rent}$$

which gives us:

$$\text{Price} \times \text{Catch} = \text{Average cost including rent} \times \text{No. of units of effort}$$

i.e., Total revenue = Total cost including rent.

If total revenue exceeds total costs, resources not in the industry will find that it is worth while to move into it, while in the reverse case some resources at the margin will be earning less than is required to retain them in the industry, and they will leave it.

Each fisherman will want to maximize the marketable value of his catch at any given level of costs. This means, on our assumptions, that

<sup>3</sup> The way in which price depends upon size and freshness can, of course, be observed but it would probably be extremely difficult to estimate how the price pattern would change following alterations in these variables. Note that freshness is related to length of stay at sea, which in turn is related to the size of ship and hence affects costs.

he will wish to maximize the weight of his catch of fish above the minimum marketable size for any given level of costs. Thus for the present argument we will assume that he will choose a mesh which limits his catch to fish above that size. If he used a smaller mesh, he would have to throw part of his catch back into the sea, which would involve unnecessary trouble.

We can now describe the equilibrium position. The minimum marketable size of fish determines mesh size. This, in conjunction with fishing effort, determines the weight of catch. This, in turn, determines total revenue which must equal the total costs of the amount of fishing involved. All this is shown in Figure 2 whose N.E. quadrant corresponds to Figure 1 and where the equality of total revenue and total costs is shown by using a 45° line in the S.W. quadrant.

As Figure 2 is drawn, either a general fall in cost or a rise in the demand for fish will cause an increase in the equilibrium catch. But if fishing effort has been carried beyond the point of maximum yield this standard conclusion does not follow, as Figure 3 shows. Here the dashed line shows one equilibrium position and the dotted line shows another; the latter corresponds to a higher level of demand, represented by the dotted total revenue curve. In this case the higher level

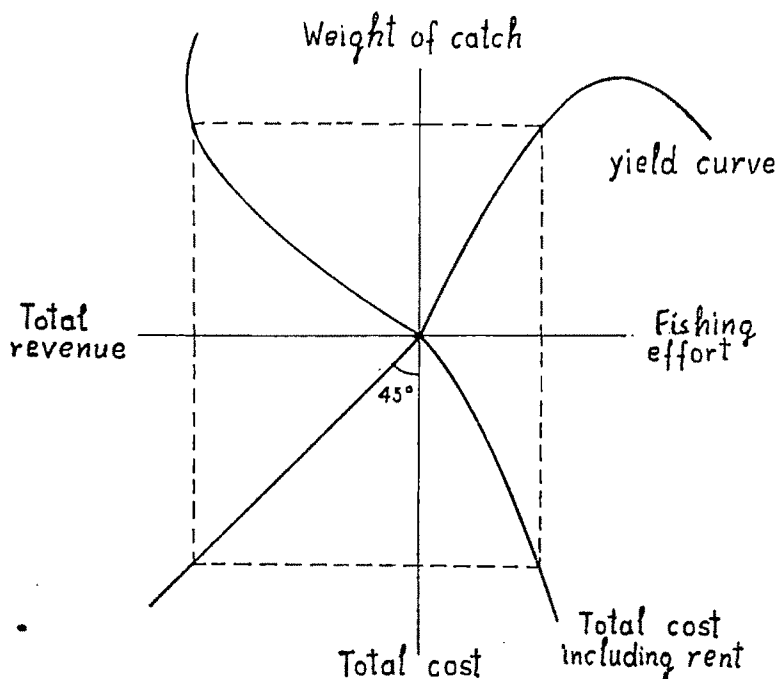

FIGURE 2

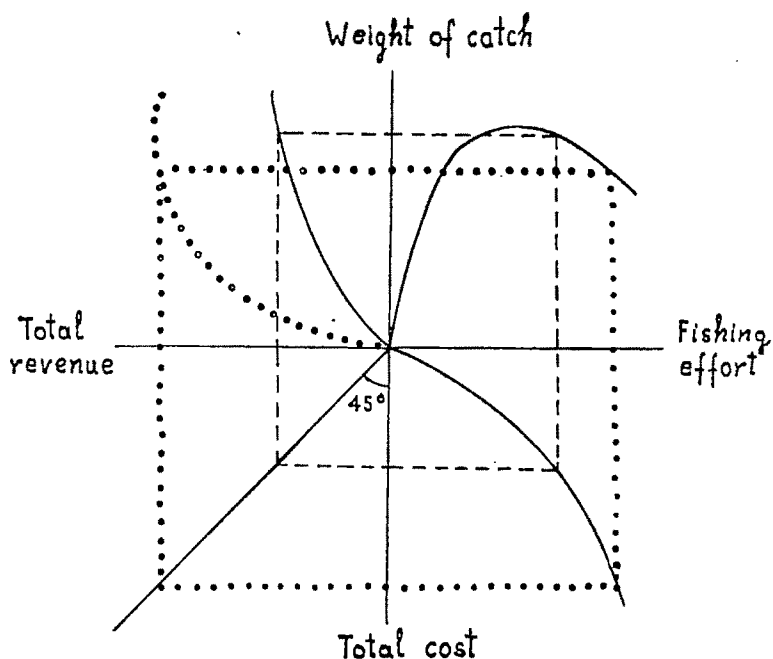

FIGURE 3

of demand means a greater employment of resources in the industry but a smaller total product!

### V. *External Diseconomies*

Such a peculiar result indicates that there is something special about the industry. There is indeed. But from what has been said it should be apparent that two problems are involved, not one. The first is that while the catch of the individual fisherman is proportionate to his own fishing effort, the same is not true of all fishermen together; i.e., the yield curves for all fishermen in Figure 1 are not straight lines through the origin.<sup>4</sup> Each fisherman imposes an external diseconomy upon his brethren; the marginal private product of his fishing effort exceeds the marginal social product.

The second problem involves mesh size. By catching small fish, fishermen are reducing the number of large fish to be caught later. If an individual fisherman were to raise his mesh size he would lose by increasing the number of hauls necessary to achieve any given weight of catch. Yet in the long run, his use of a larger mesh may lower the costs

<sup>4</sup> They are straight lines in an underdeveloped fishery where natural mortality is infinite relative to fishing mortality.

of all fishermen together and, if all of them used larger meshes, all would benefit. Here again, social and private product diverge.

### VI. *The Optimum Optimorum*

When external economies are involved both in the level of fishing effort and in the choice of mesh size, it is clear that to achieve the optimum resource allocation requires regulation of *both* these variables.

Let us assume for the present that the conditions for optimal resource allocation are fulfilled in the rest of the economy, so that no problems of "second best" arise. Let us further assume, first, that the effect of changes in the price of fish upon the distribution of real income between fish consumers and others is unimportant and, second, that a level of earnings in the industry which is equal (at the margin) to the earnings those resources could obtain elsewhere is socially acceptable. Finally, let us consider only those cases where the fishery is a very small part of the economy.

Under these conditions, the *optimum optimorum* is reached when  $G$  is maximized,  $G$  being the excess of the value of the catch to consumers over the value to them of the alternative goods and services sacrificed by devoting resources to fishing. Now the value of the catch to consumers is the maximum they would pay rather than go without it, i.e., what they do pay (total revenue) *plus* consumer surplus:  $TR + S$ , the area under the demand curve. The value of goods and services sacrificed is equal to the contribution to production that the resources used in fishing would make if they were not so used and this, on our assumptions, is what they could earn elsewhere. It is therefore measured by the total costs of the fishery *less* the rents of the intramarginal resources,  $TC - R$ . Thus the *optimum optimorum* is to be reached by maximizing:

$$G = (TR + S) - (TC - R).$$

A necessary, but insufficient, condition for maximization is that mesh size be such as to maximize the catch for the actual level of fishing effort. In terms of Figure 1 this means that the fishery must be "on" the dotted envelope curve, known as the "eumetric yield curve" (Beverton and Holt [1]). It is a property of this curve that, unlike the individual yield curves for given mesh sizes, it is asymptotic to the horizontal, thus rising throughout its length.

Figure 4 shows the determination of the optimum. The level of fishing effort,  $OF$ , must be so chosen as to maximize  $G$ . This is achieved when the slope of the  $TR + S$  curve (i.e., price per unit catch) multiplied by the slope of the eumetric yield curve (i.e., marginal social yield of fishing effort) equals the slope of  $TC - R$  (i.e., the marginal cost of

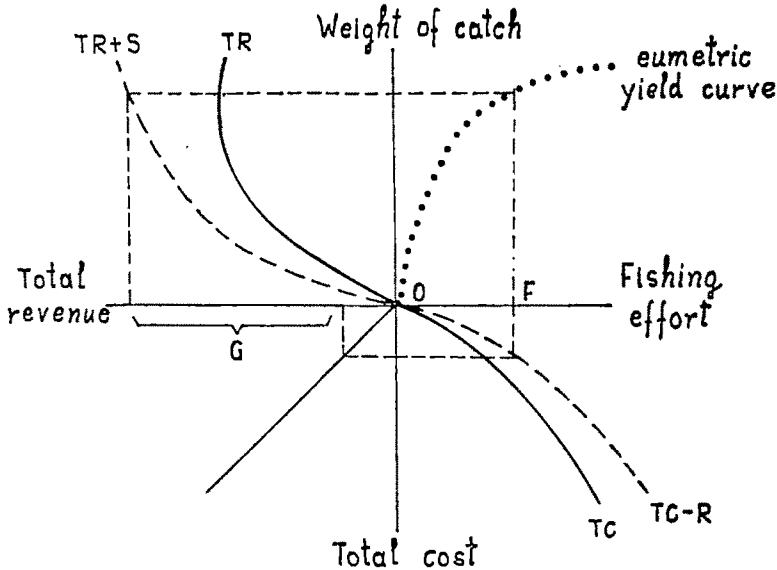

FIGURE 4

fishing effort). When this is the case, i.e., when:

$$\begin{aligned} \text{Price} \times \text{Marginal social yield} &= \text{Marginal cost of fishing effort excluding rent} \\ \text{i.e., Price} \times \text{Marginal social yield} &= \text{Average cost of fishing effort including rent} \end{aligned}$$

it must be true that:

$$\text{Price} \times \text{Average yield} > \text{Average cost of fishing effort including rent}$$

(since the average yield of fishing effort *exceeds* the marginal social yield),<sup>6</sup> which means that total revenue exceeds total costs including rent.  $G = S + R + (TR - TC)$ , the maximum gain, is the sum of consumers' surplus, producers' surplus (the rents of intramarginal labor and capital), and the rent of that other scarce resource, the fish stock.<sup>6</sup>

In an unregulated fishery, where resource allocation is nonoptimal, free entry means that total revenue will equal total costs so that no rent of the fish stock is achieved. Under these circumstances, the total gain from the fishery  $G = S + R$ .<sup>7</sup> Whether a shift from this situation to the *optimum optimum* will raise or lower the total catch (and hence

<sup>6</sup> I.e., the eumetric curve is concave from below.

<sup>6</sup> Cf. H. S. Gordon [2]. Note that if capital and fishermen of equal skill are both in infinitely elastic supply and if the fishery meets a very small part of the total demand,  $R$  and  $S$  respectively will be zero. Nevertheless, the *optimum optimum* still requires regulation of both effort and mesh size.

<sup>7</sup> Which will equal zero in the special case of the previous footnote!

$S$ ) and whether it will raise or lower the amount of fishing effort (and hence  $R$ ) cannot be determined a priori.

### VII. *Suboptimization of Mesh Size*

In order to show this it is convenient to consider the regulation of mesh size and the regulation of fishing effort separately and to show that in some circumstances these may have opposite effects. It is of great importance to consider the suboptima that can be reached by regulating only one or the other of these variables since, in practice, political and administrative considerations frequently make one or the other type of regulation impossible to introduce. This is the case, for example, with the regulation of international trawl fisheries, where agreement upon mesh size is much easier to attain than agreement about the share of fishing effort (and hence catch) to be apportioned to each nation.

When mesh size alone can be regulated, it is obvious that the fishery ought to move on to the eumetric curve, since this is the boundary of the production function. At the original level of fishing effort and costs this will raise the weight of catch but may either lower total revenue (elasticity of demand less than unity) or raise it (elasticity greater than unity). In the first case resources will leave the industry, so that fishing effort is reduced; conversely in the second case. Even in the first case, however, catch will be greater in the new suboptimum equilibrium than it was in the initial nonoptimum equilibrium. If it were not greater, total revenue would be higher or the same as before while fishing effort and total costs would be lower, so that total revenue would exceed total costs—a state of affairs incompatible with equilibrium when entry of resources is unrestricted.

Suboptimization with respect to mesh size thus involves maximizing:

$$G = S + R$$

subject to the constraint  $TR = TC$ . Moving to the suboptimum, equilibrium must raise  $S$ , since catch rises, but may either raise or lower  $R$ . If  $R$  falls, the rise in  $S$  must exceed the fall.<sup>8</sup> But if there were constant costs ( $R$  always zero) and an infinitely elastic demand ( $S$  always zero), there would be no point in regulating mesh size.

### VIII. *Suboptimization of Fishing Effort*

While, as we have just seen, suboptimizing mesh size must raise catch but may either raise or lower fishing effort and costs, suboptimizing

<sup>8</sup> Because  $TR$  and  $TC$  fall equally (by assumption);  $R$  must fall less than  $TC$  (when the supply curves of factors are rising);  $S$  must rise more than  $TR$  falls (since  $TR + S$  rises with movement down any downward-sloping demand curve).

fishing effort will always lower fishing effort and costs but may either raise or lower catch. The analysis of this case follows the same lines as that of the *optimum optimorum* (see Figure 4), save that the yield curve is not the eumetric curve but a constant-mesh yield curve. Now such a curve, as shown in Figure 1, has a maximum. If the initial non-optimum equilibrium is to the left of this maximum, suboptimizing with respect to fishing effort will *reduce* both fishing effort and catch. But if the initial equilibrium is to the right of this maximum, so that the marginal social product of fishing effort is actually *negative*, suboptimization will increase the catch. North Sea plaice and haddock are examples of trawl fisheries where fishing effort is to the right of the maximum for the mesh size in use. The classic case of this is not a trawl fishery but is said to be the Pacific halibut fishery.

How can fishing effort be regulated? The answer is surely to charge fishermen a rent for fishing, so that they economize in the use of the scarce resource. This rent would take the form of a charge per unit of weight of catch proportionate to the difference between marginal private yield (catch per unit of effort) and marginal social yield (the slope of the yield curve). The effect of this would be to raise the marginal private cost of catching fish to equal the marginal social cost.

An alternative method would be to impose quantitative restriction upon the amount of fishing effort. In practice, such restriction would produce an inferior suboptimum, unless it were so all-embracing as to amount to the institution of a sole-owner of the fishery. The reason is that any restriction must be framed in terms of a limit upon one or more of the resources used in the industry. But to ration the supply of any resource is to invite the substitution of other resources for it. Thus if the number of boats were limited, larger engines would be installed, bigger crews carried, and more resources devoted to securing a rapid turn-around in port. None of this would be efficient, in terms of resource allocation; it would simply increase the total costs of all alternative levels of fishing effort. Furthermore, it would concentrate the rent to be had from fishing economically, i.e., the gain from suboptimizing fishing effort, in the hands of the owners of the boats. In some circumstances this would be less desirable from the point of view of income distribution than a charge that placed the rent in the hands of the government which could dispose of it in a variety of ways. Thus a tax on catch is generally necessary for suboptimization. To reach the *optimum optimorum*, however, such a tax is necessary but not sufficient.

There is a great deal more that can be said about the effects of restricting entry to a fishery in ways that lead to economic inefficiency, but I shall not pursue the matter here. My purpose is merely to assert

the fundamental principle that either mesh regulation or the control of fishing effort is better than nothing but that regulation of both is still better.

### IX. *Second Best*

If the assumptions listed at the beginning of the section on the *optimum optimorum* are not met, allowance must be made for this fact in deciding policy. I do not believe that the distributional effects of changes in fish prices are worth bothering about, but there might well be circumstances in which regulation adversely affected the earnings of fishermen to an undesirable extent. Where this resulted from the creation of an excess of total revenue over total costs, the government would acquire more than sufficient funds to compensate the displaced fishermen. Where mesh regulation alone was involved, however, no such funds would be available, and the problem acquires important political elements.

Leaving these distributional questions aside, the recommendation to optimize or, if that is impossible, to suboptimize depends crucially upon the assumptions that the costs of fishing effort do reflect the value of resources in alternative uses and that the price of fish does measure the marginal contribution of fish to consumer welfare. The economist who is concerned to help formulate policy rather than to maintain his theoretical purity will, however, seek to make rough corrections for all the imperfections that he can think of in closely related markets and will then go on to make his recommendations. Thus the level of unemployment in fishing ports and subsidies or tariffs on meat and eggs are likely to draw his attention. He will, on the other hand, remain indifferent to the effects upon fishing costs of restrictive practices among suppliers of marine paint or to the effect upon the demand for fish of resale price maintenance in the confectionery trades.<sup>9</sup>

Even the purists, however, will agree that on resource-allocation grounds there are two things that can be recommended unreservedly. One is a shift to the eumetric curve and the other, as an alternative, is a reduction in fishing effort whenever the fishery is on a falling yield curve. Either of these will raise the catch and/or reduce costs, providing that "something for nothing" which alone appears to gladden the hearts of our erudite welfare economists.

There are complications, however. Even when cost, demand, and natural conditions remain constant through time so that steady state equilibrium can be achieved, the introduction of the regulation of mesh size or fishing effort will initially reduce the catch. This initial, tempo-

<sup>9</sup> Cf. E. J. Mishan [5].

rary loss clearly has to be weighed against the eventual, permanent gain. A rate of social time discount is required to make such weighing-up possible. All this complicates matters, but introduces no interesting new principles.

### *X. Alternative Methods of Regulation*

There is probably no fishery conforming to our simplifying assumptions. It is not worth while removing them one by one in a general discussion such as this, however, since the particular assumptions that should replace them will vary from one fishery to another. Thus, instead of going on to complicate the analysis,<sup>10</sup> I shall conclude by mentioning other forms of regulation than those dealt with so far. The main alternatives that have been applied in practice are: limitation of total catch, closed seasons, closed areas, minimum size limits, and the prescription of particular types of gear. These have in common that they involve no restraint on entry to the industry so that, taken alone, none of them results in the creation of a rent of the fishery. Despite this imperfection, such measures may often be better than no regulation at all, so that if one of them is all that is politically or administratively practicable there is a suboptimum to be found.<sup>11</sup> In some fisheries, two of these measures, size limits and the closure of nursery grounds, are fairly close substitutes for the regulation of mesh size, so that the type of analysis presented above can be applied. With any of them, however, total revenue and total costs will be equal in equilibrium so that the social gain to be had from the fishery is limited to the sum of consumers' and producers' surpluses:  $G = S + R$ .<sup>12</sup>

An important conclusion follows from this, as it did in the case of suboptimizing mesh size. Any measure that raises weight of catch without affecting the total cost curve will raise  $G$ . This is not unambiguously an improvement in a second-best world if resources are drawn into the industry; but if demand has an elasticity of less than unity, so that the increased catch lowers total revenue, resources will leave the industry, and the matter is simpler. Unless the immediate loss outweighs the long-run gain, the only possible objection to getting more fish at a lower cost would be that the resources in the industry deserved the rents they would lose.

<sup>10</sup> For an example, see Beverton and Holt's discussion of fisheries based on two species caught by the same gear but having different eumetric yield curves [1, pp. 388, 421, ff.].

<sup>11</sup> Furthermore, existing measures have initiated cooperation and involved a start on some of the necessary research, without either of which there is no hope of further developments.

<sup>12</sup> We are still assuming that the fishery is only a small part of the economy.

XI. *Conclusion*

I have not attempted any general survey of the economics of fishery conservation, though I hope that this article may serve as an introduction to Professor Scott's paper on the subject and Professor Crutchfield's case study of the Pacific halibut fishery, both in the proceedings of the Ottawa conference [8]. Although my exposition is mainly in terms of trawl fisheries, it can be applied more generally to other fisheries when selectivity is controllable. My purpose has been to provide an interesting and important example of the notions of optimization and suboptimization and of the proposition that coping with external diseconomies will sometimes involve interfering with the nature as well as the scale of private productive activities [6].

## BUSINESS FIRM GROWTH AND SIZE

By YUJI IJIRI AND HERBERT A. SIMON\*

It is well known that highly skewed frequency distributions, similar to the observed distributions of sizes of business firms, can be generated by a number of related stochastic processes. All of the processes have at their core something like Gibrat's law of proportionate effect—the postulate that expected rate of growth is independent of present size. Several of these processes have been offered as explanations of the observed size distributions.

Stochastic explanations for the size distribution of firms have considerable interest for economic theory and policy. They interpret these distributions in terms of the dynamics of the growth process rather than in terms of static cost curves. If the assumptions on which they rest are correct, the models call for new statistical measures of the degree of concentration and new interpretations of the economic implications of concentration. These implications have been discussed in an earlier article [4]. The present article is concerned with demonstrating that certain assumptions, known to be incompatible with the empirical data, that were used in the derivation of the earlier model (or in the description of that model in [4]) can be replaced by weaker and more realistic assumptions.

The adequacy of any theoretical explanation can be judged on two grounds: (a) the plausibility of its assumptions, their agreement with known facts; and (b) the goodness of fit of the derived distributions. Evaluating the goodness of fit of mathematical models like the ones under consideration here involves all of the theoretical difficulties of testing extreme hypotheses. Since these difficulties, although well known to mathematical statisticians, have received little discussion in the literature, we should like to pause to indicate their nature.<sup>1</sup> Suppose we wish to test Galileo's law of the inclined plane—that the distance,  $s(t)$ , traveled by a ball rolling down the plane increases with the square of the time:  $s(t) = kt^2$ , where  $k$  is a constant. We perform a large series of careful observations, obtaining a set of  $[s, t]$  pairs from which we es-

<sup>1</sup> A succinct discussion with references will be found in [2, pp. 254–56].

timate  $k$ . The actual observations cluster closely around the fitted curve, but do not, of course, all fall exactly on it. To decide whether we have confirmed or refuted Galileo's law, we test whether the observed deviations of the observations from the fitted curve could have arisen by chance. Suppose the answer is that they could. Then we may conclude either (a) that Galileo's law is correct (i.e., at least not incompatible with these data) or (b) that our observations were not accurate enough to reveal its inadequacies. The more random "noise" there is in our data, in fact, the more likely that we will decide the law has been "confirmed."

Suppose, on the other hand, that the statistical test rejects the hypothesis. Then we may conclude either (a) that Galileo's law is substantially incorrect or (b) that it is substantially correct but only as a first approximation. We know, in fact, that Galileo's law *does* ignore variables that may be important under various circumstances: irregularities in the ball or the plane, rolling friction, air resistance, possible electrical or magnetic fields if the ball is metal, variations in the gravitational field—and so on, ad infinitum. The enormous progress that physics has made in three centuries may be partly attributed to its willingness to ignore for a time discrepancies from theories that are in some sense substantially correct.

Since no one has ever formalized the criteria for ignoring discrepancies of this kind, and since the received body of statistical theory provides no suitable means for testing extreme hypotheses, we shall not test statistically the goodness of fit of the stochastic models. In the case of size distributions of firms, the observed distributions certainly "look like" Pareto, Yule, or log normal distributions, but there is no known satisfactory way to objectify the degree of resemblance. Since the observed distributions are radically different from those we would expect from explanations based on static cost curves [4], and since there appear to be no existing models other than the stochastic ones that make specific predictions of the shapes of the distributions, common sense will perhaps consent to what theory does not forbid—accepting the stochastic models as substantially sound.

Under these circumstances, however, our confidence in the proposed stochastic explanations of the size distributions may depend quite as much on how plausible we find the assumptions underlying the models as on our judgments of goodness of fit. If the assumptions are very strong, and particularly if they contradict known facts about business size and growth, we will be inclined to dismiss the stochastic explanations. If the assumptions are weak, and consistent with our empirical data, our confidence in the stochastic models will be correspondingly strengthened.

In Section I of this paper, we shall describe briefly the simplest stochastic models that have been used to derive the size distribution of firms and shall point out in what respects the assumptions incorporated in these models are contradicted by the empirical facts. In the following section we shall propose a model that removes what is perhaps the least acceptable assumption in the simple models: the assumption that the growth rates of individual firms in one period of time are uncorrelated with their growth rates in preceding periods. In the remainder of the paper, we shall examine the distributions that are generated by the improved model.

### I. Simple Stochastic Models

The simplest kind of stochastic process that will yield skew distributions like the observed ones is based on the following assumption:

*Year-to-year changes in firm sizes are governed by a simple Markoff process in which the probabilities of the size changes of any specified percentage magnitudes are independent of a firm's present absolute size.* That is, each firm, under this assumption, has the same probability as any other firm of increasing or decreasing in size by 5 per cent, 10 per cent, or any other relative amount. This is Gibrat's law in its simplest and strongest form.

Let  $i$  be a measure of firm size—total assets, say—and  $F(i)$  be the number of firms of size  $i$  or larger. (Thus, if there is only one firm of exactly size  $i$ , for all  $i=1, 2, \dots, n$ ,  $F(i)$  will be the rank of that firm in the industry.) Then, the process we have just described leads to an equilibrium size distribution which for large  $i$  is approximately:

$$(1) \quad F(i) = Ai^{-(\rho+1)}$$

where  $\rho$  is a constant that depends on the rate at which new firms enter the industry, and  $A$  is another constant. (For details, see [3] and [4].) Function (1) is the Pareto distribution and is also, for large  $i$ , an approximation to the Yule distribution. Converting to logarithms, it yields the linear relation:

$$(2) \quad \log F(i) = -(\rho + 1) \log i + \text{a constant.}$$

The observed size distributions of business firms fit equation (2) rather well (see [4]). However, distributions that are quite similar can be derived from processes based on weaker assumptions. First of all, it has been shown that we can replace the strong form of Gibrat's law, stated above, with the assumption that the expected percentage change in size of the *totality of firms in each size stratum* is independent of stratum. On this weaker assumption, the Yule, Pareto, or lognormal distributions considered in [4] can still be derived. (See [3] for more detailed discussion.) The stochastic model based on the weaker assump-

tion is obviously also consistent (as the model based on the stronger assumption is not) with the following well-known facts:

1. The transition matrices for changes in firm size from year to year show different relative (i.e., percentage) variance for the firms in different size groups—the relative variance decreasing with increase in size. Only the expected percentage changes for the totality of firms in a size group are independent of size. (See Mansfield [1]).

2. The expected rates of change are certainly not equal, or nearly equal, for all individual firms. The simplest way to show this is to examine substrata for differences in expected rate of change—for example, substrata corresponding to different industry groups.

It is not clear, however, that the weaker assumption is consistent with a third fact:

3. The expected rates of change for individual firms are not independent of changes in the prior years—there is serial correlation in the growth rates over at least short time periods.

The main purpose of the study reported here was to see whether a stochastic process based on some variant of Gibrat's law, but allowing for serial correlation from one period to another in the growth rates of individual firms, could also lead to distributions like those actually observed. If such a process could be found, it would open an additional direction for the generalization of stochastic explanations of firm size to fit a wider range of empirical findings. If it could not, grave doubt would be cast on the adequacy of stochastic models of this general kind for explaining the size of business firms.

We leave to later investigation some other important directions of generalization. In particular, the models described here do not admit mergers or decreases in size of individual firms. Our intuitions suggest that so long as the probabilities of merger or decline in size are roughly independent of stratum, they will not change much the equilibrium distributions, but this conjecture remains to be tested in future work.

## II. *A Model with Serial Correlation*

The implications of serial correlation in firm growth are not easy to trace analytically. Stochastic models admitting serial correlation have proved to be too complex to be solved explicitly in closed form for the equilibrium distributions. To cast some light on the question of whether a stochastic process with serial correlation could lead to distributions like those actually observed, we have carried out some Monte Carlo calculations with a class of processes of this kind.

In the models to be discussed here, the identity of each individual firm is maintained from one time period to the next. The change in size

of each firm is governed by a stochastic process, which depends on the size to which the firm has grown, but also upon the times at which its growth has taken place. For simplicity in our computations, we assume growth to take place in increments of unit magnitude. The probability that a firm will experience an increment in size during the next time period is assumed proportional to a weighted sum of the increments it has experienced in the past, where the weight of an increment decreases geometrically at a rate  $\beta$ , with the lapse of time since its occurrence.

We formalize these notions as follows: Let  $x_j(t)$  be the change in size of the  $j^{\text{th}}$  firm during the  $t^{\text{th}}$  time interval, where  $x_j(t)$  is either unity or zero (the firm either experiences a unit increment in size or remains the same size during any given time interval). Then the size of the  $j^{\text{th}}$  firm at the end of the  $t^{\text{th}}$  interval is simply:

$$(3) \quad \sum_{\tau=1}^t x_j(\tau).$$

The expected increment in size of the  $j^{\text{th}}$  firm during the  $(t+1)^{\text{st}}$  interval is:

$$(4) \quad w_j = p[x_j(t+1) = 1] = K(t) \sum_{\tau=1}^t x(\tau)\beta^\tau$$

where  $K(t)$  is a function of time that is the same for all firms, and  $\beta$  is the fraction that determines how rapidly the influence of past growth on new growth drops out.

Under these assumptions, large firms will, *ceteris paribus*, grow proportionately more rapidly than small firms—the *ceteris paribus* assumption being that the previous growth of the firms being compared took place at about the same times. On the other hand, firms that have experienced recent growth will grow more rapidly, *ceteris paribus*, than firms of the same size whose growth took place earlier.

We complete our model by adding assumptions about the total number of increments per time period, and the rate of entry of new firms. For simplicity in illustrating the behavior of models of this kind, we shall select the unit time interval so that there is exactly one increment per time period in the total assets of the entire industry. We shall assume that there is a constant probability,  $\alpha$ , that this increment will be allocated to a new firm (which is therefore assumed to be one unit in size at the outset).<sup>2</sup> Under these assumptions, new firms will enter at an expected rate proportional to the rate of growth of the industry.

<sup>2</sup> Thus the size unit may be interpreted as the minimum efficient size of a firm in the industry (see [2, p. 608]); and a firm of, say, 15 units may be thought of as 15 times the minimum efficient size.

### III. *Details of the Simulation Procedure*

Before we present some of the statistical results, we should like to describe in more detail exactly how the simulation of the model just described was carried out. Readers who are not primarily interested in the procedure may prefer to skip the present section.

Suppose we wish to simulate the growth of an industry from its birth to an aggregated asset size of  $N$  units. (As suggested above, a "unit" may be interpreted as the total assets required for a firm of minimum efficient size in the industry.) We allocate the  $N$  units of assets one at a time; and for convenience, we shall describe the process as if the total size of the industry grows by one unit in each "time period." Stated otherwise, we take as the  $t^{\text{th}}$  time unit ( $t=1, 2, \dots, N$ ) the period during which the industry grows from  $(t-1)$  to  $t$  in total assets. This  $t^{\text{th}}$  unit of assets is assigned to some particular firm, either a new firm (which then achieves a size of one unit) or an existing firm (which then grows by one unit during the  $t^{\text{th}}$  time period).

The allocation of the  $t^{\text{th}}$  unit is made in two stages:

*Stage I.* This stage determines whether the unit is to be allocated to a new firm or an existing firm. We first draw a random number,  $r_1$ , from a rectangular distribution between 0 and 1. If  $r_1 \leq \alpha$ , where  $\alpha$  is a given constant, we create a new firm, the  $n(t)^{\text{th}}$  firm, where  $n(t)$  is the number of firms generated during the first  $t$  periods. We assign the  $t^{\text{th}}$  unit of assets to this new firm, thus completing the allocation process for the  $t^{\text{th}}$  time period without going through Stage II. (Note that the total number of firms,  $n(t)$ , has been increased by one:  $n(t) = n(t-1) + 1$ .) If, however,  $r_1 > \alpha$ , then we assign the  $t^{\text{th}}$  asset unit to one of the existing firms, as determined by Stage II.

*Stage II.* For each firm in the industry, we keep track of two factors: the current *size* of the firm, and the current *growth potential* of the firm. By the size of the  $j^{\text{th}}$  firm at the end of the  $(t-1)^{\text{th}}$  time period,  $i_j(t-1)$ , we mean the total number of asset units that have been allocated to the  $j^{\text{th}}$  firm up to that time. By the growth potential of the  $j^{\text{th}}$  firm at the end of the  $(t-1)^{\text{th}}$  time period,  $w_j(t-1)$ , we mean a weighted sum of the asset units that have been allocated to that firm up to that time. The weights are assigned as follows: If we take as 1 the weight of the asset unit assigned during period  $(t-1)$ , then the weight of the unit assigned during period  $(t-k)$  will be  $\beta^{(k-1)}$ , where  $\beta$  is a proper fraction. That is, prior growth is assumed to create potential growth at a rate that falls off geometrically with the lapse of time since the prior growth occurred. We also keep track of the sum of the growth potentials for all firms:  $w(t-1) = \sum_j w_j(t-1)$ .

To assign the  $t^{\text{th}}$  asset unit to a firm, we draw another random number

$r_2$  from a rectangular distribution between 0 and  $w(t-1)$ , and assign the unit to the  $k^{\text{th}}$  firm, where  $k$  is the largest integer which satisfies

$$\sum_{j=1}^k w_j(t-1) \leq r_2.^3$$

Then, the probability that the asset unit will be assigned to any particular one of the existing firms is proportional to the weight of that firm.

Thus, at the end of the  $N^{\text{th}}$  period, all  $N$  units of the assets of the industry will have been allocated among  $n(N)$  firms. The distribution of assets is given by  $i_j(N)$  ( $j=1, 2, \dots, n(N)$ ). Then  $F(i)$  is the number of firms whose size at the end of the  $N^{\text{th}}$  period is greater than or equal to  $i$ .

Since Stage II of the process requires that there already be some firms in existence, the scheme is started off by providing a small initial population of firms. The initial conditions used in most of our simulations specified three already existing firms, one of 5 units, one of 3 units, and one of 1 unit. The final distribution is not entirely independent of the initial conditions, but tends to become independent as  $N$  grows large. (Except for the few largest firms, the distribution is very insensitive to the initial conditions even for a relatively small  $N$ .)

#### IV. *A Distribution Generated by the Model*

As a first example of a distribution generated by this process, we consider a sample of 247 firms whose aggregate size,  $N$ , is 1,000 asset units, or an average of about 4 units per firm.<sup>4</sup>

The weights were reduced at a rate of 5 per cent per time period [ $\beta=.95$ ]. Table 1 shows the frequency distribution of firms by size. The largest firm is 56 units. At the other end of the scale, there are 110 firms of one unit each. As is characteristic of these models, the distribution is highly skewed and the cumulative distribution is approximately linear on a double log scale (Figure 1). Thus, the introduction of the weights did not change the general character of the equilibrium distribution.

<sup>3</sup> For reasons of speed, the actual computation is a little different. Instead of recomputing each of the weights each time period, we simply increase the *new* weights geometrically with time. Thus the asset unit allocated during period  $t$  is assigned a permanent weight of  $\gamma^t$  where  $\gamma=1/\beta$ . Clearly, this leads to exactly the same probability of each firm being allocated the new asset unit, for all weights, under the modified scheme, are multiplied by the same factor,  $\gamma^t$ .

<sup>4</sup> In generating this particular sample,  $\alpha$  was not strictly constant but was set at  $n(t)/t$ . (The usual initial conditions, described in the previous section, were imposed to start the process off.) In generating the other samples reported here,  $\alpha$  was fixed at a constant value. This change in assumption did not noticeably change the qualitative characteristics of the sample.

The final weights, after 1,000 time periods, were very far from proportional to the sizes of the individual firms. A mere 16 firms, out of the total of 247, accounted for almost all the potential for future growth. Each of these 16 firms had 1 per cent or more of the total of weights. The remaining 231 firms had, *in the aggregate*, only about 1 per cent of the total weight. Thus, at  $t=1,000$ , there was about one chance in four that the next increment would go to a new firm, since  $\alpha=.247$ ; if it did not, there were 99 chances in 100 that it would go to one of the 16 firms with non-negligible weights. These sixteen firms ranged over the whole size distribution: one was of size 39, one of size 12, one of size 7, one of size 5, two of size 4, four of size 3, and three each of sizes 2 and 1. In fact, these sixteen "growing" firms formed a skew distribution of almost the same shape as the entire distribution of 247 firms.

We see that Gibrat's law was very far from being satisfied for the individual firms. However, the growth potential was widely distributed over the size strata. In Table 1 we also show (column 4) the aggregate

TABLE 1—DISTRIBUTION OF FIRMS BY SIZE IN A SIMULATED "INDUSTRY" OF 247 FIRMS

\* Less than .001

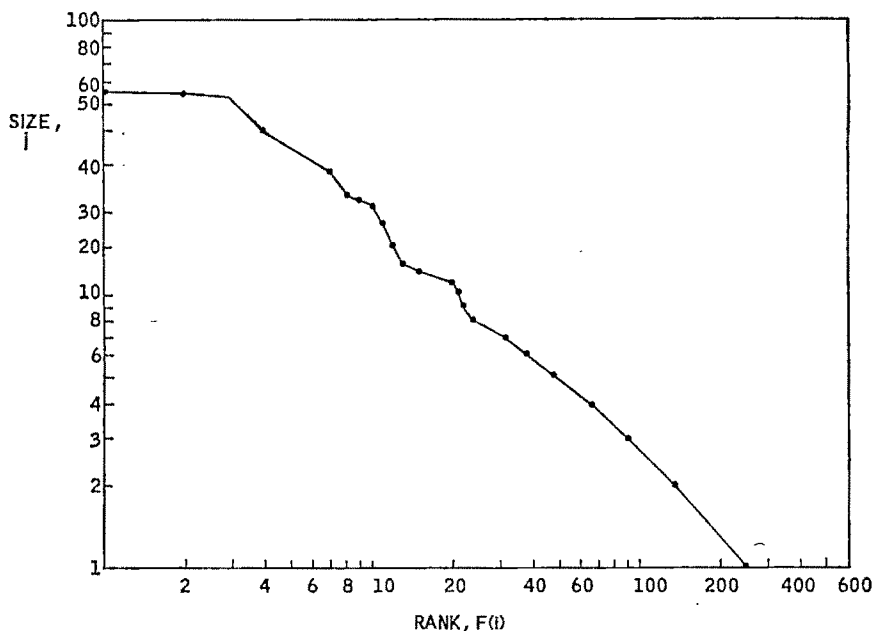

FIGURE 1. RANK-SIZE DISTRIBUTION OF SIMULATED "INDUSTRY" OF 247 FIRMS

of weights for all firms above a given size, and (column 5) the aggregate size of all firms above a given size. Thus, firms of size 28 and larger account for 27.3 per cent of the total weight, but 28.5 per cent of the total "assets." Their growth potential, in the aggregate, was therefore only slightly less than that postulated by Gibrat's law. The corresponding figures for firms of size 10 and larger are 38.0 per cent and 48.6 per cent, respectively; for firms of size 5, 43.0 per cent and 65.2 per cent, respectively; and for firms of size 3, 76.9 per cent and 79.6 per cent, respectively. Middle-sized firms, then, show less than average growth potential, firms of size 2 to 4, greater than average potential, firms of size 1, less than average.

#### V. *The History of a Simulated Industry or Economy*

To get a better understanding of the growth patterns produced by the model, we made additional runs, recording the sizes of individual firms at successive time intervals. Data are presented in Table 2 from a run of 1,000 time units, with  $\alpha$ , the probability of assigning the next increment to a new firm, set at .2; and  $\beta$ , the rate of discounting past growth, set at .95.

The table shows the sizes, at each 100 time intervals, of the 20 firms (out of a total of 209) that reached a final size of more than ten units. A number of interesting observations can be read from this table. Let

us call the 20 firms whose histories are recorded in the table the "large" firms. First, older firms had not much greater chance of becoming large than younger firms. Eleven of the large firms entered the system in the first half of the time interval, and nine in the second half—an insignificant difference. There was some underrepresentation, among the large firms, of the very youngest; only three firms among the youngest 60—i.e., the firms numbered 150 to 209—had reached the large size.

If we consider the eight largest firms, those of size 20 and over, there is a little more relation between size and age. The very largest firm was the first to enter the system, and three other very large firms were among the first 50 to enter. On the other hand, the second and third largest firms are relative newcomers, having appeared during the last 40 per cent and 30 per cent of the system's history, i.e., after times 600 and 700, respectively.

We see, further, that firms which grow large experience most of their growth during the first 200 or 300 time periods after they enter

TABLE 2—GROWTH PATTERN OF 20 LARGEST FIRMS IN A SIMULATED "INDUSTRY" OF 209 FIRMS

Firm Number (in order of entry)	Period Ending at Time:

the system, then reach a plateau. The very large size of Firm 1 is associated with an abnormally long period of rapid growth (See Table 3 and Figure 2). The firm grew at a virtually constant percentage rate until its growth stopped. Table 3 shows how, during its period of growth, its weight (probability of being chosen for the next increment) remained in the range .1 to .3. When the weight dropped, virtually to zero, during the seventh period, the growth stopped abruptly.

We do not wish to defend in detail the realism of the assumptions of the model or of the histories it produced. The time discount rate,  $\beta$ , was almost certainly too high—underestimating the advantage of established firms—as compared with most real-life situations. What is interesting, however, is that a stochastic process that admits this very strong effect of recent growth in the determinants of future growth still produces the familiar kinds of skewed equilibrium distributions. Clearly, Gibrat's law does not have to be assumed in any of its strong forms to produce this result.

#### VI. *Effects of Parameters on the Distribution*

A substantial number of additional simulation runs, varying the parameters  $\alpha$  and  $\beta$ , provide information about the dependence of the equilibrium distribution upon these parameters. All of the cumulative distributions have a strong resemblance to that depicted in Figure 1. They are almost linear on a log scale. As  $\alpha$  increases, the rank-order distributions (the distributions of  $F(i)$ , see Figure 1) acquire somewhat smaller initial slopes,<sup>6</sup> and become slightly more convex to the origin. As  $\beta$  decreases, the distributions again become considerably more con-

<sup>6</sup> By initial slope we mean the angle of the curve to the horizontal axis at the bottom of the graph whose ordinate is  $\log i$  and whose abscissa is  $\log F(i)$ .

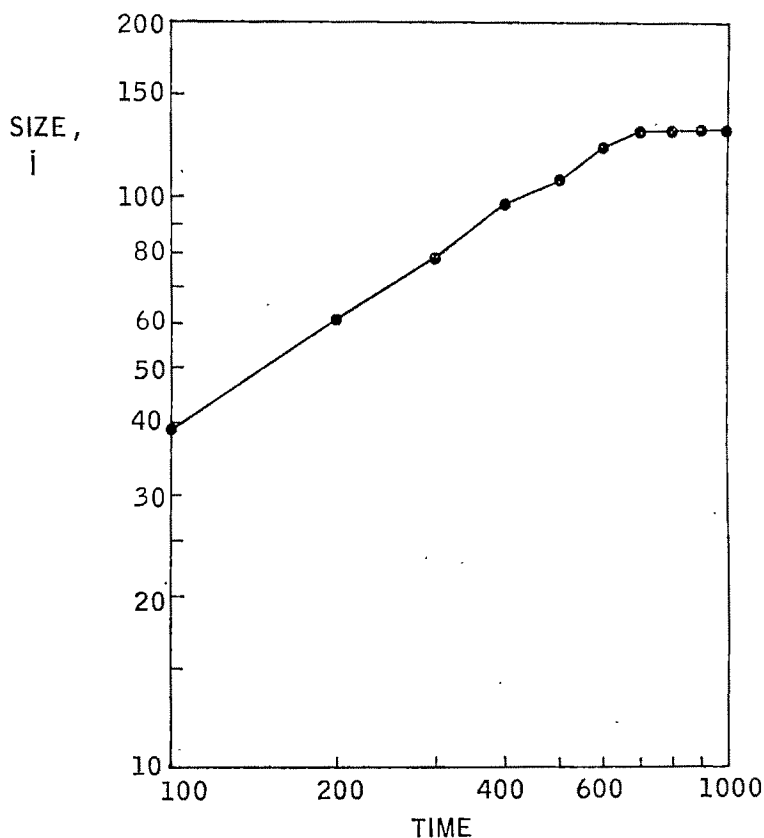

FIGURE 2. GROWTH OF LARGEST FIRM IN A SIMULATED INDUSTRY

vex to the origin, but acquire slightly *larger* initial slopes. The reciprocals of the slopes correspond to the parameter  $-(\rho+1)$  in the equations (1) and (2). For the case where  $\beta=1$ , it can be shown that  $\rho=1/(1-\alpha)$ . The parameter  $-(\rho+1)$  can be estimated, in the neighborhood of  $i=2$ ,

TABLE 4—ESTIMATES OF  $-(\rho+1)$ , FOR VARIOUS VALUES OF  $\alpha$  AND  $\beta$   
 $[-(\rho+1)=d \log F(i)/d \log i]$

$\alpha$	$\beta$			
	.95	.99	.999	1
.1	.65	.91	.86	.99
.2	.81	.9	1	1.2
.4	1.15	1.2	1.2	1.4

by the equation:

$$(5) \quad -(\rho + 1)_2 = \frac{\log F(1) - \log F(2)}{\log 2}.$$

The values of  $-(\rho + 1)_2$  for various combinations of  $\alpha$  and  $\beta$  are given in Table 4. They range from .65, for  $\alpha = .1$ ,  $\beta = .95$ , to 1.4 for  $\alpha = .4$ ,  $\beta = 1$ .

### VII. Conclusion

In this paper we have described a new stochastic process, and have shown, by numerical simulation, that it generates equilibrium distributions that closely resemble the Yule distribution. In this process the expected growth rates of individual firms are assumed proportional to weights, where the weights are the time-discounted sums of previous increments in size. Thus the process incorporates a significant modification of the law of proportionate effect that allows substantial differences in the expected growth rates of individual firms.

The behavior of the new model is consistent with the empirical observation that the growth of firms, deviating from the predictions of a simple one-period Markovian process, exhibits strong serial correlation in the size changes of individual firms. We can now confidently predict that many other processes, incorporating comparably weak forms of the law of proportionate effects, will lead to highly similar equilibrium distribution. Thus our analysis greatly increases the plausibility of a stochastic explanation for the observed distributions of firm sizes.

## The Unimportance of the Embodied Question

In a recent article in this journal, Moses Abramovitz noted that Robert M. Solow and I obtain different estimates of the effect on economic growth of alternative investment rates because of different appraisals of the importance of embodiment of new knowledge in capital goods. Abramovitz suggested "an issue of first-rate importance is, therefore, posed" [1, p. 773]. Recent literature seems to imply that the issue can be resolved by discovering what fraction of developments that can potentially raise productivity must be embodied in capital. I wish to suggest here that the whole embodiment question is of little importance for policy in the United States; that the issue is not usefully formulated in terms of the fraction of progress that is embodied; and that the right question can't be answered beyond a showing that it is unimportant.

The argument that the question was of no great consequence that was given in my *Sources of Economic Growth* may be stated as follows [2, pp. 234-37, 254-55]. The embodiment effect operates through the age distribution of the gross capital stock of business. This distribution can be summarized accurately enough by average age, provided weights of different types of capital goods (particularly structures and equipment) are held constant. Suppose then the growth rate of output per man is 1.6 per cent a year, of which .6 per cent is due to advances in knowledge (my estimates for the 1929-57 period). Suppose we can change the average age by one year from 1960 to 1970.<sup>1</sup> In so far as productivity-changing developments are embodied, we will then be working in 1970 with the technology that we would be using in 1971 if average age did not change. If nothing is embodied, the change in average age of capital will not affect output. If all advances of knowledge but not other productivity-affecting developments are embodied, 1970 output will be .6 per cent higher than if nothing is embodied and the 1960-70 annual growth rate .06 percentage points higher. If *everything* affecting output per man favorably or unfavorably is embodied, 1970 output will be 1.6 per cent higher as a result of the reduced age of capital and the annual growth rate .16 percentage points higher. If half of either is embodied, the amounts will be half as large. After 1970 the growth rate will be the same as otherwise unless the average age is again changed. Thus the most extreme assumptions yield annual growth rates, calculated over a ten-year period, that differ by .16 percentage points for each year that the average age of capital changes; thereafter, for as long as the new average age is maintained, the levels of national income differ by a constant 1.6 per cent.

The force of the calculations depends on the fact that average age is a

<sup>1</sup> If average age (and the rate at which knowledge advances) does not change between dates or assumed situations, the calculated growth rate is the same whether advances are or are not embodied in capital.

variable that does not and can not vary much under normal conditions, so that one year is a big change. This is especially the case with equipment, for which the age level is short and observed variation small. Commerce Department calculations [5, p. 17] based on Bulletin F lives give an average age for equipment of 7.2 years in 1961 and a range of 1.5 years during the period since 1929. An alternate calculation based on assumed lives 20 per cent shorter gives an average age of 5.6 years and range of 1.2 years. Ranges even as large as these were possible only because of the extreme variation in gross capital formation due to the depression of the 'thirties and war.

Equipment, quite reasonably, is usually stressed, but some attention is given to structures. Their age is longer and the range greater. If structures and equipment are weighted by value of gross stock (surely the maximum weight that can be assigned to structures), based on an average of 1929 and 1961 weights in 1954 prices, extreme ranges of 2.6 and 3.6 years are given by the alternative estimates. Both extreme ranges include 1945. From 1929 to 1961 the change was only .3 years by one estimate and 1.0 years by the other.<sup>2</sup>

Such data illustrate how insensitive is the age of equipment, and even of plant and equipment, to big swings in the rate of gross investment. Edmund Phelps has also shown that average age is independent of the equilibrium (or average) level of capital formation and tends to return to an equilibrium point, so that sustained changes are hard to obtain [6]. This is borne out by the actual data.

The purpose of the present note is to argue that, though such calculations and considerations themselves assign no large importance to the embodiment question unless rates of technological progress well outside the bounds of experience are assumed, they overstate its significance by what I should judge to be an enormous amount. To speak of technological progress embodied in capital is simply to refer to changes in the quality of capital goods. The index of quality change in capital goods is the quotient of indexes of the quantity of capital goods when capital of different vintages is equated (1) by ability to contribute to production, and (2) by production cost at a common date.<sup>3</sup> Ordinary observation indicates that the amount of quality change in any time period must vary enormously among different types of equipment or structures, ranging from zero for many types of capital that aren't changed to huge amounts for a few types. The profitability of replacing any capital good (or complex of capital goods) before it is physically worn out depends directly upon the extent to which its quality falls short of the quality of its potential replacement. If an industry invests \$50 million, profit maximization will lead it to replace those types of capital in which quality improvement (hence obsolescence) is greatest. An extra \$10 million will go to capital in

<sup>2</sup> These average lives are computed from stock estimates derived by the perpetual inventory method. Lives were probably extended during the war, so the divergence between 1945 and more normal periods is probably understated.

<sup>3</sup> That is, quality change is the quotient of indexes of capital computed by methods 3 and 1 in the language of an earlier article [3], where the meaning of these indexes is specified more fully.

which quality improvement is smaller, and so on. Moreover, a particular type of capital good acquired for replacement will be applied first to uses where the gains from replacement are greatest. Also, the mix of capital goods, and consequently the average quality change, varies greatly among industries; hence so does the average profitability of replacement of capital. Industries in which average quality of new capital goods changes most will, other things equal, have the highest replacement rate. Any reasonable amount of gross investment in the economy will already provide for taking up those investment opportunities arising because quality change in capital goods is large: i.e., within firms and industries, large relative to all capital used; and, as among industries, large relative to the average industry.

It follows that if we suppose \$50 billion of investment in the economy will embody 25 per cent more technological progress than \$40 billion—an assumption which would be consistent with calculations made earlier based on average lives—we shall have a radical overestimate. Within ranges of gross investment worth talking about—that is, above some reasonable minimum, certainly above the point of no net capital formation—I should think the additional amount of technological progress that will be incorporated into production at a higher investment rate rather than a lower rate must be very small relative to the amount incorporated at the lower rate. We can legitimately take only a small fraction of the .16 previously computed as the difference between the 10-year growth rates if everything or nothing is embodied (given a one-year change in average age) because that calculation assumed quality change on incremental investment to be the same as on average gross investment. All the calculations I have seen on embodiment effects assume the same rate of quality improvement for all capital goods, hence are great overestimates.<sup>4</sup>

The same reasoning disputes the importance of the idea that a high rate of gross capital formation is necessary in order to get radically improved equipment into use quickly so that, with experience in its use, further technological advance will be accelerated. Any attention to rates of return will tell us that introduction of capital goods representing radical improvement over those previously available will be made at even a low rate of gross capital formation. There may be cases of radically improved capital goods whose merit is not obvious to potential buyers, so that attachment of a high risk premium makes their introduction marginal, but the point hardly deserves much weight.

I have explained why the embodiment question appears to me unimportant in the United States at present. The same reasoning shows it would not be helpful to know the fraction of “technological progress” that is, or must be, embodied. We are dealing not with a two-way classification but with a curve of rates of return. Some innovations (the purely unembodied) require no gross investment, and their introduction, if computed against capital cost (other costs may be involved), yields an infinite rate of return. Others (I suspect a great many) require some trifling readjustment of existing capital or insignificant capital expenditure to achieve a substantial continuing gain; these imply a near-infinite rate of return on capital if we compare the effects

<sup>4</sup> In addition to Solow [7] and myself, I may refer specifically to W. A. Eltis [4] and Phelps [6].

of making or not making the capital expenditure, but will be made routinely with scarcely a thought to capital cost or total capital budget. In a two-way classification these are embodied, but the fact is of no significance. We then move down to those changes requiring appreciable investment, which must be expected to yield rates of return ranging from very high down toward zero.

If one seriously wished to measure the embodiment effects of having (say) \$50 billion instead of \$40 billion of gross investment a year, he would need (1) to specify the composition of the extra \$10 billion in terms of types of capital goods; and (2) to measure the quality improvement in these capital goods. The first is difficult, the second, I have argued [3, pp. 229-34] and am convinced, impossible.

Calculations that assume (1) that quality improvement in capital is necessary for all productivity increase and (2) that quality improvement in (say) the first \$40 billion of gross investment is no larger, per dollar, than in the next \$10 billion, yield results that are, I believe, enormously too large. They are useful only because they yield such small numbers that we can deduce that the true figures must be insignificant under normal circumstances in the United States.

There is an important reservation to universal application of the conclusion that it makes little difference to analysis whether or not one takes account of embodiment effects. It need not hold in countries where (or times when) capital goods are used much longer than in the present-day United States (hence have more room for variation) or their age distribution is greatly distorted and where (or when) tendencies toward equalizing rates of return are (or recently have been) extremely weak because of lack of competition or because of controls on investment. These conditions existed to a degree in the United States in the immediate postwar years, their effects on short-term productivity changes perhaps being important until around 1950. Because specific investment controls during the war and wartime demand patterns prevented the introduction of new capital in the industries serving postwar markets, at war's end there presumably was a significant backlog of high-yielding investment opportunities deriving from improvement in capital goods. This was reflected in a catching-up of productivity, particularly from 1948 to 1950. Opportunities deriving from previous improvement in capital goods are therefore significant in examination of the early postwar period. A one-year change in the true average age of equipment had a different effect than in normal times; and the change recorded by the available capital stock estimates probably understates the change in average age that actually took place.<sup>5</sup>

EDWARD F. DENISON\*

<sup>5</sup> Note, however, that if average age is understated in the immediate postwar period, the size of the gross stock is also understated.

### The Stability of Neutralism: A Geometrical Note

Suppose two powerful, industrialized countries, called Usonia and Russonia, compete by means of capital exports and other forms of "aid" for influence in various underdeveloped countries, typified by Thirldonia. We are interested in exploring whether anything can be said about the resulting relations between total aid, the proportions of the total supplied by each of the powers, the political position of Thirldonia, and particularly about the stability of that position. Usonia and Russonia, even though antagonistic over a wide range of issues, may come to perceive a community of interest in such stability, or at least in the avoidance of utter instability, for sudden large-scale changes in alignment on the part of Thirldonia could increase the risk of war between the two powers to a point not desired by either.

Aid from each of the two powers is likely to be influenced by the political alignment of Thirldonia as expressed, for example, by the proportion of votes it casts in the United Nations General Assembly in line with Usonia's or Russonia's wishes. Aid received from Usonia may be assumed to be the larger, the more closely aligned Thirldonia is with Usonia, with a similar aid-giving behavior holding for Russonia. For the time being, we shall suppose that complete alignment with Usonia yields the same flow of aid as does complete alignment with Russonia.

Figures 1a, 1b, and 1c portray some of the principal resulting possibilities when political alignment is shown on the horizontal axis and the amount of aid received on the vertical axis. In Figure 1a aid from Usonia declines linearly and aid from Russonia increases in the same fashion, as Thirldonia takes up political positions farther removed from Usonia and closer to Russonia; in Figure 1b aid from both decreases little as Thirldonia moves toward neutralist middle ground; while in Figure 1c aid is cut to the bone as soon as Thirldonia ceases to be a faithful camp-follower. The total aid flow available to Thirldonia results from adding up the two individual aid flows from Usonia and Russonia and is shown as the heavy line or curve in the figures: It is invariant with respect to political alignment in 1a, and exhibits either a maximum or a minimum for the neutralist position depending on whether the

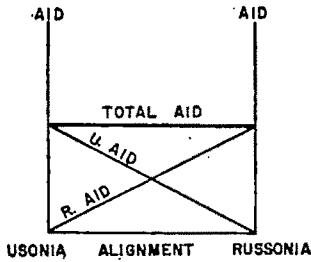

FIGURE 1a

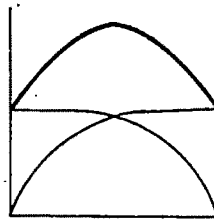

FIGURE 1b (NPN)

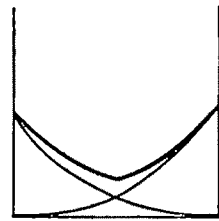

FIGURE 1c (PN)

TYPES OF SYMMETRICAL AID-GIVING BEHAVIOR BY USONIA AND RUSSONIA

aid-giving behavior of the powers corresponds to the one portrayed in 1b or in 1c.

We have just derived the transformation curve or opportunity-set available to Thirdonia if aid-from-Usonia and aid-from-Russonia are considered as two commodities which can be "produced" in differing combinations, depending on the country's position between the two powers. The three possibilities just discussed are shown along traditional lines in Figure 2 where one of the two commodities is measured along the horizontal and the other along the vertical axis. Aid-giving behavior of Figure 1b which does Not Penalize Neutralism (NPN) is now seen to result in the traditionally shaped transformation curve, while 1c-type insistence on substantial identification on the part of the aid-givers results in the opposite shape (labeled PN for Penalization of Neutralism).

Consider next the preference functions of Thirdonia for aid from Usonia and Russonia. Again we may distinguish between three principal possibilities shown in Figure 3. First, Thirdonia may be exclusively interested in maximiz-

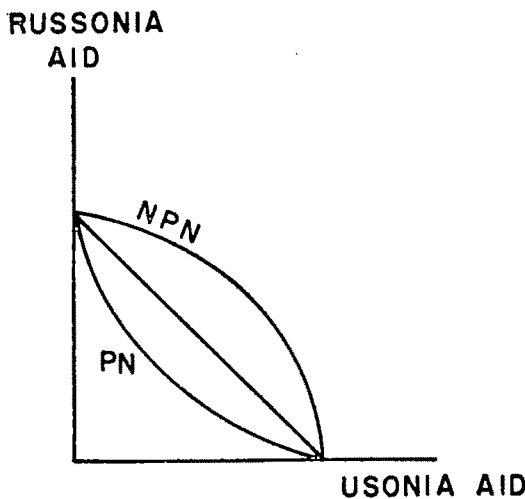

FIGURE 2. THIRDONIA'S OPPORTUNITY-SETS

ing aid: in this case its indifference map will consist of straight lines such as *MM* (for Mercenary Maximization of aid) forming a  $45^\circ$  angle with the axes along which the two aid flows are measured. The next possibility is that a country puts a high value on independence as well as on aid and feels that, for any given total, its independence is the greater, the more the ratio of Usonia aid to Russonia aid approaches unity. Such a preference would result in the traditionally shaped indifference curve, labeled *AI* (for Aid plus Independence).

A third conceivable preference pattern exists. Thirdonia could prefer complete alignment with one of the two superpowers to a middle position, either

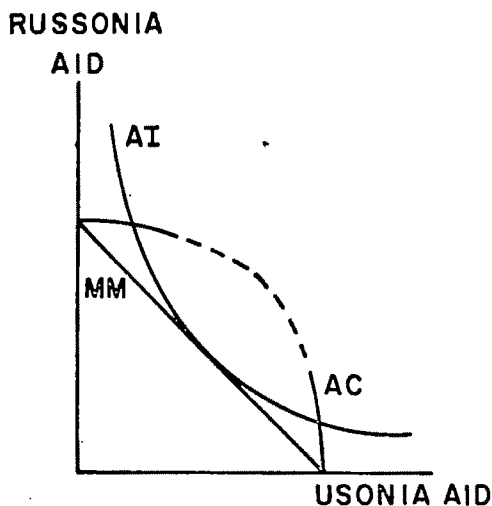

FIGURE 3. THIRDONIA'S INDIFFERENCE FUNCTIONS

because it has a liking for a strong, ideological stance or because it does not wish to be suspected of playing Usonia off against Russonia for the sake of material advantage or for some other reason. Given any fixed amount of aid, the country prefers getting it all from one source rather than through any combination of the two aid-givers. The resulting shape of the preference pattern is shown in the curve labeled *AC* (for Aid plus Commitment); the middle portion of this curve is dotted to indicate that, at any point of time, a country exhibiting this preference pattern is likely to find itself on one or the other end of the curve and is likely to visualize only immediately adjacent positions.

We can now join our "transformation" and "indifference" curves (Figures 2 and 3), and one important result follows immediately. The traditional point of stable equilibrium is achieved by joining the *NPN* curve of Figure 2 with the *AI* curve of Figure 3. In other words, if Thirdonia's preference pattern is such that it values both aid and independence, a stable point is best achieved through aid-giving behavior on the part of Usonia and Russonia that does not

penalize neutralism. Should aid be reduced strongly as soon as Thirldonia ceases to be wholly aligned with one or the other aid-giving powers (curve *PN* of Figure 2), then a potentially unstable situation results from the *AI*-type of preference. The highest *AI* curve could touch the *PN* curve at two widely distant points, between which the aid-receiving country would be indifferent. Even if there is only one point of tangency, small real or imagined shifts in the position of the two similarly shaped curves could produce a drastic shift of the optimal point, i.e., a sudden switch in Thirldonia's position in relation to the two superpowers. Hence, if an underdeveloped country is known to have the Aid-plus-Independence type of preference and if both Usonia and Russonia, in the interest of reducing the risk of war, are intent on preventing sudden shifts in the world power balance through shifts of positions on the part of less developed countries, then they ought to adopt the aid-giving behavior of Figure 1b, which does not penalize neutralism.

Looking at some of the other conceivable combinations of the transformation curves of Figure 2 and of the indifference curves of Figure 3, we find that Mercenary Maximization (*MM*) of aid is compatible with stability only if neutralism is not penalized (*NPN* curve of Figure 1). Small real or imagined shifts in the supply curve of aid of a linear or *PN* type could produce a complete flip-flop on the part of a country that is only interested in squeezing the maximum aid out of the two competing powers.

What happens if a country puts a positive value on ideological commitment to one of the aid-giving powers and hence has a preference function of the *AC* type? In this case, the more stable situation appears to result from the transformation curve following the *PN* rather than the *NPN* type. In other words, if Thirldonia likes commitment, the most stable situation is created through the aid-giving countries responding to and reinforcing this attitude by penalizing decisively any straying from the commitment path. It is possible to speak of stability in this situation only if Thirldonia, which is by definition aligned with one of the aid-giving powers at the outset, does not visualize a switch all the way to the other camp (its preference curve is defined at any one time only for one or the other end of the *AC* curve of Figure 3).

At this point in our reasoning we perceive that, in contrast to the usual assumption of economic theory, the shapes of the transformation and indifference curves in our model are *not* independent: clearly, the *NPN* and *AI* curves, on the one hand, and the *PN* and *AC* curves, on the other, "belong" together and generate each other. A Thirldonia with the *AI*-type preference will see its behavior rewarded and its correctness confirmed by finding that its opportunity-set is in fact *NPN*; and the realization on the part of Usonia and Russonia that Thirldonia is *not* "playing off one against the other," but is genuinely interested in keeping at an equal distance from both, may induce them to adopt the kind of aid-giving behavior that does not penalize neutralism. On the other hand, the *AC*-type of preference on the part of Thirldonia will generate expectations of unbending loyalty on the part of the country to which it professes to be committed; should these expectations be disappointed ever so little, aid is likely to be reduced drastically, in accordance with the *PN* pattern.

Unstable situations exist nevertheless and can now be viewed as a result of transitional departures from the two basic stable situations, *NPN-AI* and *PN-AC*. Suppose we start out with preference system *AC* and opportunity-set *PN*. An unstable situation can then arise because Thirdonia shifts its preference pattern to *AI* while Usonia and Russonia hold fast to *PN* instead of switching to *NPN*. A potentially unstable situation results, in other words, if a previously committed country shifts to a neutralist or independent position and its previous mentor cannot reconcile itself to the loss of its dominant influence and attempts to coerce the country back to the fold. The possible, and indeed likely, result is that the country will move even farther away.

Another case of instability would occur in the following situation: Suppose

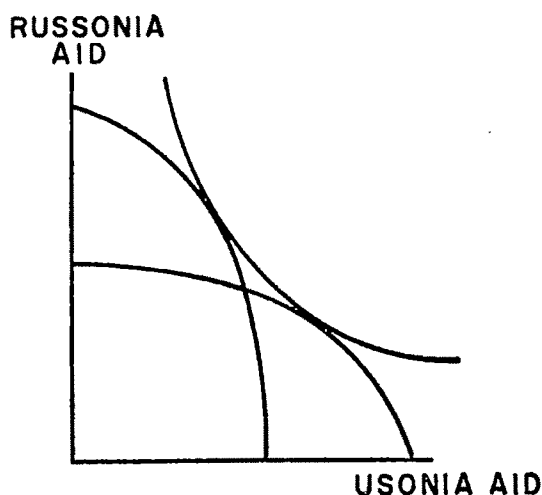

FIGURE 4. TWO EQUALLY NEUTRALIST THIRDONIAS  
WITH DIFFERENT OPPORTUNITY-SETS

Thirdonia has the neutralist *AI*-type of preference, but the aid-giving countries have adopted the *NPN* aid-giving behavior simply as a means of cajoling Thirdonia into becoming a satellite; after a while they may then tire of waiting for this hoped-for event and try a more coercive policy of the *PN* type—Thirdonia's choice would be unpredictable.

The model could no doubt be complicated considerably in various ways, for example, by introducing time more explicitly into the analysis. Suppose that the longer Thirdonia continues as Usonia's or Russonia's satellite, the more it will tend to be taken for granted with a consequent decline in aid received—such aid-giving behavior could easily be shown to give rise to instability.

Another realistic complication of the model may be briefly discussed. Suppose that the maximum aid flow that can be obtained by Thirdonia I from Usonia is larger than that which Russonia can be expected to provide, while the opposite holds for Thirdonia II. This means that the opportunity-set

facing these two countries is no longer symmetrical with respect to the coordinates. Figure 4 assumes that the relevant opportunity-sets are of the *NPN* type and that both Thirdonias have the same neutralist *AI*-type preference pattern. It is clear then that the two countries will select different foreign policy positions and would receive their aid in different proportions from the two superpowers even though they have basically the same neutralist attitude. For this reason, it is impossible to detect (to "read off") the extent or sincerity of their neutralism merely from the proportion of total aid received from one of the two contenders for influence (or from the proportion of votes cast in the United Nations General Assembly in line with the wishes of either Usonia or Russonia).

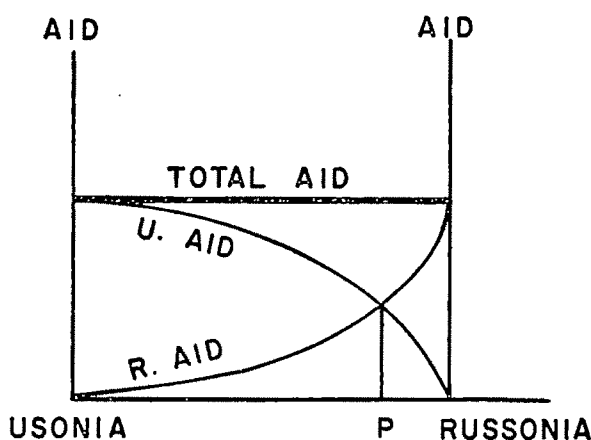

FIGURE 5. ASYMMETRICAL AID-GIVING BEHAVIOR

Thus far we have assumed (see Figures 1a, 1b, and 1c) that the aid-giving behavior of Usonia and Russonia is symmetrical. Naturally this need not be—indeed is not likely to be—the case. An interesting combination results if Usonia exhibits the *NPN* behavior of Figure 1b and Russonia the *PN* behavior of Figure 1c. The outcome could well be, as shown in Figure 5, that total aid will once again be invariant with respect to Thirdonia's political alignment. If Thirdonia is neutralist and therefore has the *AI*-type preference function, it will now select the political position that will equalize aid from both camps and will therefore tend to take up the political position *P* on Figure 5, rather close to Russonia. This situation will be exasperating to Usonia whose contribution to Thirdonia's development equals that of Russonia. As a result, Usonia will now be tempted to imitate Russonia and withdraw to the *PN*-type of aid-giving behavior. This sequence would lead to the unstable *AI-PN* combination we have already discussed. Suppose, however, that instead of Usonia adopting Russonia's behavior, Russonia for some reason goes over to Usonia's *NPN*-type behavior; we would now be back to the stable *NPN-AI* combination, and Thirdonia would assume a truly neutralist position, equidistant from both blocs. The irony would be, in this case,

that Russonia's more generous aid-giving policy would have led Thirdonia to move politically away from Russonia.

Another step toward the real world is taken if we allow for multilateral aid agencies or for aid-giving countries other than Usonia and Russonia. Taking the most worrisome unstable case where a neutralist country faces aid-giving behavior that penalizes neutralism (the *AI-PN* combination), it appears that the function of multilateral aid or of aid from countries other than the two superpowers may well be to restore stability by stepping up aid from these sources as Thirdonia moves to neutralist ground. In this way the total aid available to Thirdonia from all three sources of aid could approximate the *NPN* rather than the *PN* shape and stability would be restored. It is conceivable that Usonia and Russonia, realizing the domestic policy constraints under which they operate, find it difficult in their bilateral relations with Thirdonia to adopt anything but the *PN*-type of aid-giving behavior; it would then make good sense for them to foster deliberately multilateral aid or aid from other industrial countries in such a way as to compensate for their inability to make their own bilateral aid-giving behavior conform to the requirements of stability.

Finally, it might be tempting to analyze how the behavior of each of our three principal actors is shaped by expectations about that of the other two. But before the resulting complications are explored, it was perhaps worth while to show that a simple static model can account satisfactorily for a variety of real-life situations and can even yield some suggestions for policy.

### Cost Functions and Progress Functions: An Integration

The relationship between unit production costs and the level of output per production period has come to be depicted in economic analysis by U-shaped or L-shaped functions, indicating that, as the level of output increases, unit costs fall over a certain range and then either rise or remain constant. In engineering studies, the relationship between unit production costs and the level of output has come to be depicted by hyperbolic "learning curves" that show unit costs declining as accumulated total output increases over time. The apparent incongruence of these two conceptions has stimulated at least one major econometric study [5] and two serious attempts at a theoretical integration [1 and 6] [4]. The purpose of this note is to present a straightforward algebraic and graphic integration of static cost functions and dynamic progress functions and an illustration of the empirical relevance and interpretative usefulness of these analytical constructions.

#### I. The Cost-Output Relation

The static cost function of economic theory does not require elaborate exposition; the standard reference is the well-known article of Viner [8], supplemented by the more recent contribution of Wolfson [9]. A few fundamental features of the static cost concept of special relevance for the present

analysis may be briefly summarized:

(1) The static cost curve is a picture of alternatives; each level of cost and output is an alternative to every other level.

(2) Static short- and long-run cost functions are not sequentially related in time, as they would be if, for example, the firm could or must move automatically from one function to another.

The progress functions<sup>1</sup> used in engineering cost studies relate the level of unit production costs to the accumulated level of output over the entire sequence of time periods during which production takes place. Typically, a hyperbolic function is assumed or estimated and graphed as a straight line on log-log paper. As generally used, progress functions take no account of the time rate of production per period; thus, it is assumed either (a) that the time rate is constant or (b) that unit cost levels are unaffected by the time rate.

Progress functions may be computed both in terms of average unit accumulated costs (total accumulated costs divided by total accumulated output) and average unit costs per production run or time period. The cost concept used makes a difference in the position of the progress function but not in its algebraic slope. If the cumulative unit cost function is written:<sup>2</sup>

$$c = aV^b,$$

the period unit cost function is

$$c_t = a(1 + b)V^b.$$

## II. A Simple Model

Our suggested integration of the static cost function and the progress function involves three variables: the level of period production costs, either total ( $C_t$ ) or average ( $c_t$ ); the level of output per production period,  $q_t$ ; and the accumulated level of total output,  $V$ .<sup>4</sup>

The general pattern of anticipated relationships between period production costs, period output, and accumulated output is illustrated in Figures 1 and 2.

<sup>1</sup>The most comprehensive general treatment of progress functions or learning curves is that of Asher [2]. The outstanding article in the engineering literature is Conway and Schultz [3]. For an evaluation of applications of the concept and a comprehensive bibliography see [7].

<sup>2</sup>For derivation see [5b, p. 137].

<sup>3</sup>Unhappily, the word "slope" has come to be used in the engineering literature to refer not to the algebraic slope of the progress function, the exponent  $b$  in the log-log transformation, but to the ratio between unit production costs at any particular level of accumulated output and unit production costs at a level of accumulated output one-half as great. For example, if a doubling of output results in a 20 per cent decline in unit production costs, the slope of the progress function is said to be 80 per cent. Slopes of 70-90 per cent are typical for the progress functions reportedly discovered and used in engineering cost studies. Evidently, for a given hyperbolic function, there is a direct correlation between the value of  $b$  and the slope in this sense—if  $b = -0.322$ , the slope is 80 per cent, etc. Hirsch has suggested the term "progress ratio" as a substitute for the present use of the term "slope" in the engineering literature, and "progress elasticity" for the value of the exponent  $b$  [5b, p. 138].

<sup>4</sup>Contrast should be noted with the Cooper-Charnes analysis [4] in which *time* is the second explanatory variable and the Alchian-Hirschleifer analysis [1, 6] which uses a capital value measure of cost.

In Figure 1 total period production costs are shown composed of fixed costs per production period, invariant with respect to both current and accumulated output, and variable costs that rise at a gradually increasing rate as the volume of output per period increases. The cost surface slopes downward as  $V$  increases, so long as the cost-reducing progress in production technique continues.

In Figure 2 the relationship is pictured in terms of unit costs. Here the familiar U-shaped curve is depicted for familiar reasons: the "spreading" of fixed costs and the gradually rising rate of variable costs. This cost surface

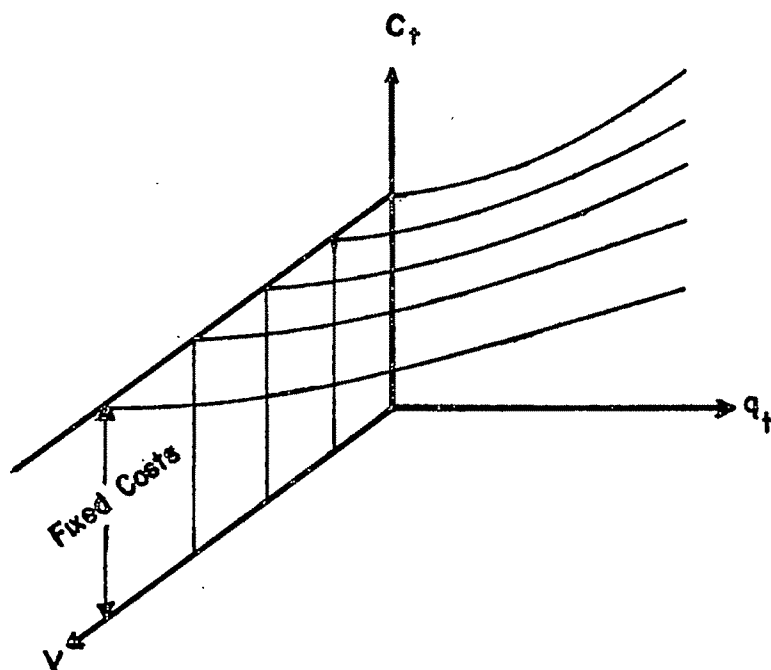

FIGURE 1

is also downward sloping with respect to  $V$ . In addition, the surface may flatten and the minimum-cost level of period output may shift as  $V$  increases. These effects would depend, of course, on the underlying technology and the particular form that the cost progress takes in individual circumstances.<sup>5</sup>

The plot of accumulated output levels and unit cost observations forming the basis for the usual "learning curve" may now be understood as a series of points on a cost surface like that in Figure 2. The same may be said of the schedules of unit costs and period outputs examined by economists in search of evidence of economies of scale. Whether the usual simplifications of either profession constitute *oversimplification* in particular circumstances is a

<sup>5</sup> The illustration reflects the accumulation of output over discrete production periods. Thus at each level of  $V$  the function is defined for all values of  $q_t$ . If we assume continuous production and instantaneous accumulation of output, the function is undefined for all values of  $q_t$  greater than  $V$ .

matter for empirical investigation; the general model of the cost-output relation should include both significant variables.

The cost-output relation depicted here is conceived in terms of a series of short-run production periods. It is explicitly *not* the traditional long-run cost curve of economic theory. The concept of the long run refers fundamentally not to the passage of calendar time but to the length of the planning horizon with respect to the variability of all factors of production. It is not necessary to proceed in time from one short-run cost curve to another in order to attain any particular position on the long-run curve. It is, however, necessary to

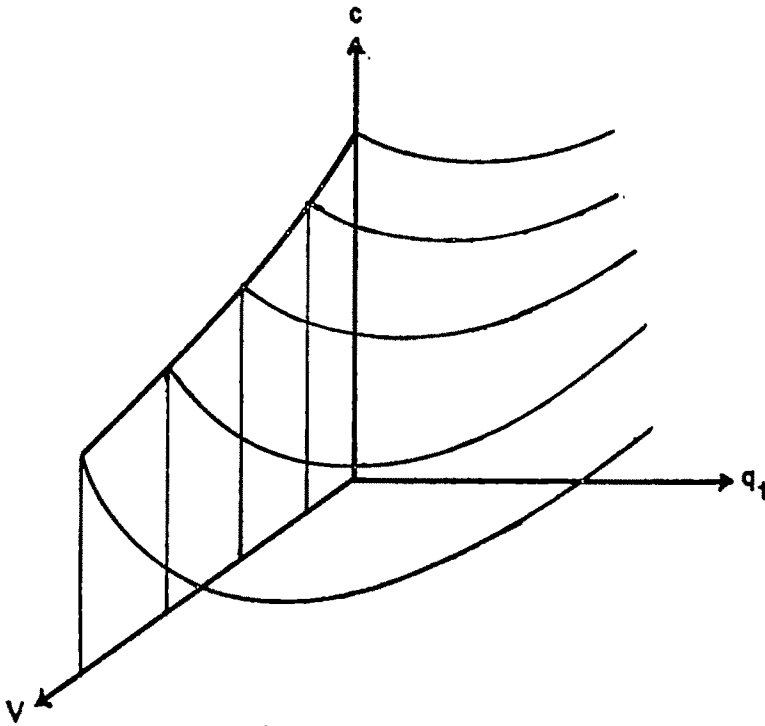

FIGURE 2

proceed in time through one short-run production period after another in order to obtain an accumulated level of output, and thus to experience the reduction in unit cost levels that results from accumulated production experience. Indeed, it may be that the cost-output surface is not fully determinate unless the particular time sequence of period outputs is specified.

### III. *An Illustration*<sup>6</sup>

The cost-output relation suggested here has been tested by application to several collections of production and cost data for manufacturing activities. Only one of these applications will be reported in detail.

<sup>6</sup>Data analyzed here were obtained by E. C. Keachle in the course of research reported in [7].

A total of 22 observations were obtained for total unit production cost, unit labor cost, and volume of output per production run for the production and assembly of five different pieces of radar equipment. The production technology was similar in all cases, and the five sets of data were reduced to a single series of cost-output observations for purposes of analysis. Output, unit cost, and unit labor cost on the initial production run for each piece of equipment were designated 100, and all subsequent cost and output values were converted to an index on this basis. From examination of the data, it was determined that the rising phase of the short-run cost curve would not be observed with sufficient frequency to permit estimation.

The variables were defined as follows:

$X_1$  = unit labor cost

$X_1'$  = unit total cost

$X_2$  = lot size (i.e., the volume of output per production period)

$X_3$  = cumulative quantity.

Because we do not know the exact shapes of the functions, for each of the cost variables three regressions were computed:

- (1) unit cost as a function of the logarithms of lot size and cumulative output;
- (2) unit cost as a function of the inverse of lot size and cumulative output;
- (3) the logarithms of unit cost as a function of the logarithms of lot size and cumulative quantity.

Five significant regression equations were obtained. In one regression (equation 1a) the lot size variable proved to be insignificant.

The five equations, with standard errors and levels of significance of the regression coefficients and coefficients of multiple determination, are shown in Table 1. All of the regression coefficients are significant at the 5 per cent level or better, and all of the correlations obtained are high. As may be observed from a direct comparison of the regression coefficients (because the variables are measured in the same units) and from a comparison of the Beta coefficients shown in Table 2, cumulative output is in all instances a more powerful explanatory variable than lot size. The increase in the Beta coefficients for lot size in regressions 2b and 3b over the corresponding coefficients in regressions 2a and 3a indicates that the relative importance of lot size as an explanatory variable is greater for unit total cost than for unit labor cost; the relative importance of cumulative quantity is correspondingly less. This result indicates that the decline in unit costs attending the accumulation of output over time is well described as a "learning" phenomenon; the accumulation of output experience is a more important explanation of changes in *labor* costs than of changes in total costs.

These results both confirm and extend those obtained by Hirsch. His analysis was cast entirely in terms of unit labor cost, and he found neither lot size nor size of plant to be a significant variable [5a, p. 145]. Similar results have been obtained by us from the analysis of other data and in one of the tests computed here. However, as our results show, there are instances in which the volume of output per production period exerts a significant and in-

(2a)	$X_1 = 27.23 - 1489.47X_2^{-1} - 5922.05X_3^{-1}$ (527.06) (694.15) (.02) (.001)	$R^2 = .90$
(2b)	$X_1' = 41.99 - 1491.57X_2^{-1} - 4420.79X_3^{-1}$ (479.53) (631.55) (.01) (.001)	$R^2 = .88$
(3a)	$\log_e X_1 = 7.01350 - .181532 \log_e X_2 - .344730 \log_e X_3$ (.08184) (.06050) (.05) (.001)	$R^2 = .90$
(3b)	$\log_e X_1' = 6.29088 - .169311 \log_e X_2 - .202341 \log_e X_3$ (.05682) (.04200) (.01) (.001)	$R^2 = .90$

\* Both variables significant at the 5 per cent level or better in all equations. Results for regression (1a) excluded because variable  $X_3$  failed to meet required significance levels.

dependent effect upon unit costs beyond the effects due to increasing cumulative output.

#### IV. Implications

The inclusion of both the cumulative level of output and the level of output per production period as significant variables in the explanation of the level of unit production costs has important implications for both teaching and research. Judging from current textbooks and casual observation, the "learning" phenomenon receives almost no mention in the standard treatments of production costs in economics or industrial engineering courses. This neglect of the principle of "progress in technique" in the classroom is reflected in the neglect of the differing ages and production histories, as well as sizes, of plants and firms in empirical studies of scale economies. Although accumulated production know-how has long been accepted as an advantage of established firms over new entrants, the importance of production history, in addition to or instead of capacity or output level, as an explanation for cost

TABLE 2—BETA COEFFICIENTS

Equation Number and Dependent Variable	Lot Size	Cumulative Quantity
1b—Unit total cost	-.31	-.67
2a—Unit labor cost	.26	.77
2b—Unit total cost	.32	.71
3a—Unit labor cost	-.28	-.71
3b—Unit total cost	-.38	-.61

differences has rarely been specifically investigated. As a result, some of the evidence that has been taken to reflect economies of scale may in fact reflect the accumulation of experience by long-established large firms and plants. If so, then available estimates of minimum optimal scale of production may be *high*; long-established, large firms and plants may have low unit costs because of their past output experience, not because of their present size.

The importance of "progress functions" as described here for the explanation of cost behavior within the plant and firm also carries implications for macroeconomic analysis. Hirsch [5b, p. 155] has pointed out the relevance of "learning" considerations in the forecasting of cost and labor requirements on industry-wide and economy-wide bases. In addition, progress in technique due to "learning" may need to be considered as a third variable, along with autonomous technological progress and research and development activity, in explaining changes in the aggregate production function and differences between rates of economic growth, both over time and between countries. The widely held view that the pattern of long-term economic change in the United States is more largely due to the increasing productivity of the workforce than to increasing capital per worker may be, in part, a macroeconomic reflection of the "learning" phenomenon. The existence and form of such relationships, if any, will require careful investigation. As a beginning, the inclusion of accumulated production experience along with "scale" and "production technology" as determinants of the efficiency of the fundamental production unit suggests the possibility of these macroeconomic effects and also suggests a reassuring symmetry between the analysis of production in the small and in the large.

### Capital Gains and the "Life Cycle" Hypothesis of Saving

In the March issue of this *Review* Professors Albert Ando and Franco Modigliani presented empirical estimates of aggregate consumption functions which included net worth as an explanatory variable [1]. They used Goldsmith's estimates of national wealth [3] [4] to test some of the implications of the Modigliani and Brumberg consumption model [6] [7].

Similar empirical results were obtained (from net worth data in [4] [5]) in my study [2], which was independent of, but is parallel to, that of Ando and Modigliani. There is one basic conceptual difference, however, between the two studies, but apparently it does not lead to very different empirical results. In the Ando and Modigliani study, net worth for the period is based upon the *average* price during the year; therefore, their measure of net worth for the period *includes* the impact of net worth changes due to price level movements during the period, i.e., includes the gains for the period. My study examines net worth based upon the price at the *beginning* of the year ( $A_{t-1}$ ) and includes capital gains on this net worth ( $G_t$ ) as an explicit exogenous variable in the consumption function. There are other minor differences in definitions and in the time covered by the data, but the basic difference lies in the inclusion in the consumption function of the capital gains variable and the estimation of its impact upon consumption. (It should be noted that in the Ando and Modigliani model it is not necessary to make explicit reference to these capital gains since their model implies that such gains will affect present and future consumption insofar as they change the value of net worth.)<sup>1</sup>

Given this conceptual difference, I fitted a consumption function of the following form:

$$C_t = B_1 + B_2 Y_t + B_3 A_{t-1} + B_4 G_t.$$

This function was fitted both in money and real values; Tables 1 and 2

<sup>1</sup>At one point there is some confusion when they seem to imply that changes in net worth result only from the current period's saving; they state that  $A_t = A_{t-1} + S_t$  (where  $A_{t-1}$  is the initial net worth of the period;  $A_t$  is the ending net worth of the period; and  $S_t$  is saving during the period; cf. [1, p. 69, fn. 26]); however, either their definition of saving includes changes in the value of net worth due to price level movements or else they may be assuming that real changes in the purchasing power of net worth do not exist (an assumption of homogeneous price movements). This point was not clear. In my model, however, this difficulty is avoided by defining the period's saving in more conventional terms as the difference between disposable income and consumption; therefore, the change in net worth from the beginning of the period to the end would be the period's saving *plus* the period's capital gains or losses ( $G_t$ ); i.e.,  $A_t = A_{t-1} + S_t + G_t$ .

F		.3720 (.1482) 2.510	.0732 (.0203) 3.597	.0279 (.0170) 1.636	2.525 (1.235) 2.047	.995

Note: Upper figure is estimated coefficient. Middle figure is standard deviation. Lower figure is  $t$  statistic.

\* The basic regressions were also computed with data weighted (divided) by initial net worth; however, the empirical results were about the same as those presented in this table and are consequently not reproduced here.

present the statistical results.<sup>2</sup> The data are shown in Table 3; they are approximately the same as those of Ando and Modigliani with some definitional exceptions. All observations are on a per capita basis (i.e., all data are deflated by population). The variable time ( $T_t$ ) is included in the regressions to test whether initial net worth is significant only as a proxy for secular growth. Ordinary least-squares estimation was used; some regressions omit the constant term ( $B_1$ ) in order to have the same form as Ando and Modigliani's consumption function.

The estimated coefficients of income and initial net worth are different from zero as in the Ando and Modigliani study. My estimates differ slightly from theirs, probably because of the different definitions of variables<sup>3</sup> and because of the different time periods used.

<sup>2</sup> In the original study, saving was used as the dependent variable. Tables 1 and 2 are based upon these results but with consumption as the dependent variable.

<sup>3</sup> For a complete discussion of the definitions of the variables used in this study see

TABLE 2—REGRESSION RESULTS: REAL VALUES<sup>a</sup>

F		.6548 (.1350) 4.850	.0349 (.0258) 1.351	.0125 (.0209) .598	.950 (5.435) .1749	.992

Note: Upper figure is estimated coefficient. Middle figure is standard deviation. Lower figure is  $t$  statistic.

<sup>a</sup> The basic regressions were also computed with data weighted (divided) by initial net worth; however, the empirical results were about the same as those presented in this table and are consequently not reproduced here.

The estimated coefficient of the capital gain variable is positive, but the hypothesis that such gains have no effect upon consumption ( $B_4 = 0$ ) cannot be rejected. However, one implication of the theoretical model is that unanticipated gains have a "one-shot" effect to be spread over the remaining life of the individual. They become part of net worth in future periods and therefore affect consumption in the same way as initial net worth, as Modigliani and Ando imply. This would mean that the coefficient  $B_4$  should equal  $B_3$  (unless there is a period of adjustment; this possibility is discussed below). One can test the hypothesis that the two coefficients are equal by rewriting the consumption function as  $C_t = B_1 + B_2 Y_t + B_6(A_{t-1} + G_t) + B_7 G_t$  and

[2, Part B of the Appendix]. Apparently there are differences between the definitions used here and in the Ando and Modigliani study [1]. For example, their definition of income is labor income only, while mine is the more conventional disposable income. The complete sources and definitions of their data are also to be published shortly—see the references given in [1].

testing the hypothesis that  $B_7$  equals zero. This equation was estimated in the original study [2]. The coefficient  $B_7$  is slightly negative but not significantly different from zero.<sup>4</sup> Regression  $B$  implies that the coefficient of capital gains is not significantly different from zero; the test of  $B_7$  implies that the coefficient of capital gains does not differ significantly from that of initial net worth. The test is not of sufficient power to make the distinction between the two hypotheses.<sup>5</sup>

\* For a detailed source of data, see [2, Part B of the Appendix].

<sup>b</sup> Includes consumer durables net of replacement cost depreciation.

<sup>c</sup> These gains were computed by taking the change in initial net worth for the year and subtracting saving for the year from this difference.

The results in real terms (Table 2—deflation was by the consumer price index of 1958 base) are about the same as those of Table 1. The only basic difference lies in the definition of real capital gains which are not simply money gains deflated by a price index.<sup>6</sup> (See Table 3 for the values of the

<sup>4</sup> If one assumes that the capital gains are received evenly throughout the period rather than entirely at the beginning of the period, one could plausibly assume that the coefficient on capital gains should be one-half that on wealth to reflect the fact that the household adjusts to the average level of net worth, i.e.,  $B_4 = \frac{1}{2}B_5$ . This possibility was also considered and the hypothesis that  $B_5 - 2B_4 = 0$  could not be rejected.

<sup>5</sup> Also, there are very few degrees of freedom in these tests (although more observations were used in the original tests [2] with essentially the same results), and such estimating techniques do present statistical difficulties as were pointed out in the Ando and Modigliani study.

<sup>6</sup> Money capital gains were computed by subtracting money saving of the period from the change in the money values of initial and ending net worth.

$$G_t = A_t - A_{t-1} - S_t.$$

Real capital gains were computed by subtracting real saving of the period from the change in real purchasing power of ending net worth and of initial net worth. The consumer price index was the deflator.

$$G_t = \frac{A_t}{P_{t+1}} - \frac{A_{t-1}}{P_t} - \frac{S_t}{P_t}.$$

For a detailed discussion of this variable, see [2, Part B of the Appendix].

real capital gains.) Again the capital-gain coefficient cannot be distinguished from that of net worth or from zero. When the variable "time" is included in the function, initial net worth is still a significant variable, implying that net worth is not merely a proxy for some growth item.

I would, therefore, conclude that the omission of capital gains as an explicit variable in the Ando-Modigliani study does not greatly affect the empirical results; in fact the results would tend to justify their treatment of such gains as a part of wealth. Capital gains appear to encourage more consumption in the current period. They will certainly do so in future periods when such gains are part of future net worth, which has a significant effect upon consumption. However, even with the inclusion of this variable, the statistical results of both studies are about the same for the variables of income and initial net worth.

### The "Life Cycle" Hypothesis of Saving: A Correction

In the March, 1963 issue of this *Review*, we presented an aggregate theory of consumer behavior based on considerations of households' life cycle of income and of consumption needs, as well as some empirical tests.<sup>1</sup> At that time, we were unaware of the existence of revised data on net worth of consumers prepared by Goldsmith and Lipsey.<sup>2</sup> We also had some numerical errors in adjusting the old, now obsolete, data by Goldsmith to fit our framework. We have prepared new estimates of the basic parameters, using the revised data by Goldsmith and Lipsey, and they are reported in Table A.

<sup>1</sup> Albert Ando and Franco Modigliani, "The 'Life Cycle' Hypothesis of Saving: Aggregate Implications and Tests," *Am. Econ. Rev.*, March 1963, 53, 55-84.

<sup>2</sup> The new data were kindly provided for us by Dr. Lipsey of the National Bureau of Economic Research. They have since been published in Raymond W. Goldsmith, Robert T. Lipsey, and Morris Mandelson, *Studies in the National Balance Sheet of the United States*, Princeton, 1963.

Table A is identical in construction to our original Table 2. Comparison of the two tables indicates that our revised results are not appreciably different from the original ones, though they appear to be somewhat more satisfactory in a number of respects as noted below:

1. There is no longer any evidence of a significant downward shift in the coefficient of labor income from the prewar to the postwar period. In every instance the estimated shift is of negligible magnitude and is but a small fraction of its standard error. In the case of the coefficient of net worth, where a shift could be due to differences in the method of estimating net worth, the hypothesis of a downward movement cannot be rejected outright but the evidence is much less convincing than before.

2. In the case of hypothesis I, the various methods of estimation yield values of the parameters which are both appreciably closer to each other and more in line with a priori expectations. In particular, the constrained regression (3), the first difference method (6), and the ratio estimates (11), which are supposed to bracket the true value, yield an estimate of  $\alpha_1$  in the immediate neighborhood of .6 with a range of .09 (instead of around .5 with a range of .12), and an estimate of  $\alpha_3$  ranging between .072 and .08 (instead of between .072 and .105).

3. The revised data provide somewhat stronger support for hypothesis II than did the original ones, as the coefficient of  $Y(L/E)$  is in every instance both numerically larger and statistically more significant (though the outcome is reversed for the coefficient of  $L/E$  in the ratio estimates). We also note that the estimate of  $\alpha_1 + \alpha_2$  remains in the neighborhood of .7 but the range of the estimates from the above-mentioned three methods is reduced from .10 to .07. Finally the coefficient of net worth moves closer to the estimates obtained for hypothesis I and to a priori expectations, averaging now just over .06 with a range of .016, instead of .05 with a range of .03. Thus the new estimates of the parameters for both hypotheses I and II seem to be considerably more reliable, a conclusion reinforced by the substantial improvement in the Watson Durbin Statistic.

On the whole, in the light of these results, we see no reason to change any of the conclusions we stated in our original paper.<sup>3</sup>

ALBERT ANDO AND  
FRANCO MODIGLIANI\*

<sup>3</sup> We should like however to take this opportunity to clarify one passage in our paper which might give rise to misunderstandings. In footnote 30, for the purpose of examining certain long-run implications of the life cycle hypothesis, we made use of the equation:

$$S_t = A_t - A_{t-1}.$$

In general, of course, saving,  $S$ , which we define as current income minus current consumption, need not coincide with the change in the value of assets, on account of capital gains (or losses). In writing the above equation we abstracted from capital gains, which we feel is justified for purposes of long-run analysis, although we should have made this assumption explicit.

### Public Policy Problems of the Domestic Crude Oil Industry: Comment

The recent article by Paul Davidson in this *Review* [4], while illuminating certain aspects of crude oil policy, is seriously defective in one vital area. A failure to perceive clearly the relationship between ultimately fixed supplies and Ricardian rent payments completely vitiates his rather striking conclusion concerning the effect of depletion allowances on the allocation of resources to exploration.

He points out that the supply of oil-bearing land in the United States is fixed and that nothing man can do will change it. This simple observation leads him to the conclusion that, given perfect competition, certainty, etc., the major (or total) effect of depletion allowances is to increase rents accruing to owners of subsurface mineral rights. Depletion allowances lead to either no or very little more exploration (and development?) than would otherwise be carried on.<sup>1</sup>

The conclusion is strikingly at variance with that reached by the most authoritative academic students of the industry, DeChazeau and Kahn, who feel that depletion allowances are part of a "powerful inducement to look for oil and gas" and that they "undoubtedly have the effect of enhancing the flow of capital into crude oil exploration and production and hence of holding the price of oil lower than it otherwise might be" [5, p. 221]. Harberger, who is cited as partial authority for their statement, feels that depletion allowances probably lead to too much exploration and development [6, p. 447]. A long list of what Davidson calls "apologetic 'scholarly' support" could be cited in favor of the conclusion.

Numbers, however, do not make a case and it is necessary to examine carefully the arguments advanced. The critical assumption underlying Davidson's conclusion is that the supply of new oil land is perfectly (or nearly perfectly) inelastic. On what does he base this assumption? First, his "own acquaintance with the crude oil industry" leads him to disagree with Harberger's conclusion that there is a substantial degree of elasticity in its supply [4, pp. 102-3, n. 20]. Secondly Harberger's statement that the amount of oil underground is a fixed physical quantity apparently adds to his conviction. Thirdly, his view is apparently confirmed by the feeling that:

The landowner of any undeveloped oil property [Davidson really means the owner of the subsurface mineral rights] exhibits a perfectly inelastic supply function for his mineral rights—there is no alternative use. Thus, the lease bonus and royalty payments are, as McKie and McDonald intimate, Ricardian rent payments [4, p. 104].<sup>2</sup>

<sup>1</sup> Compare these statements: "... our analysis has indicated that, in the long run, percentage depletion *does not significantly encourage* the allocation of additional real resources to exploring presently nonproductive oil lands" and "A reduction in the depletion allowance *will not reduce* the incentives to explore undeveloped oil lands" [4, p. 107, italics added].

<sup>2</sup> He seems also to have been misled by the purely coincidental fact that the "value" of the depletion allowance is roughly equal to the typical producing royalty of  $\frac{1}{8}$ . See [4, p. 104, n. 21 and p. 106, n. 23]. While it is not true that the owner of mineral rights can do nothing but lease them (he can drill them himself, or keep them in the hope that their

Assuming homogeneity, Davidson's argument then follows nicely. If all land is homogeneous, with only one use, it is a free good up to the point where it is all being used, and thereafter rent payments accrue to holders of claims to land. Below the fixed limit a subsidy to the purely competitive land-using industry will increase land use; beyond the limit it will simply increase rents accruing to claim holders. If any rent is currently being paid, the land must be currently in perfectly inelastic supply.

The difficulty lies in the fact that "oil land" (by which Davidson seems to mean all land which either does or may overlie crude oil pools [4, p. 102]) is in no sense homogeneous. Some 80 per cent of the area of the United States and continental shelf is potentially oil bearing, but no two acres have exactly the same potential. Given the level of geological knowledge it is possible to rank very crudely and tentatively the potentially oil-bearing acres into a potential profitability continuum. The attractiveness of an area will depend, *inter alia*, on the expectation of finding oil there, the likely depth of the oil, if found, and the anticipated size of fields. Given the price of oil, areas can be roughly ranked according to the expected profitability of surveying and drilling in them. The ranking may be turned upside down by putting the question in the form "What is the expected cost of finding an extra barrel of reserves in each of the different areas?" All the potential oil areas can thus be ranked in a continuum according to, *inter alia*, the number of feet that will probably have to be drilled in order to find one extra barrel of oil.<sup>3</sup>

While the above is greatly simplified, it nevertheless constitutes a reasonable approximation of the situation. Great uncertainty prevails and "rankings" are subject to considerable change as surveying and nearby drilling make more knowledge available. Absolute certainty cannot be achieved except by drilling on the spot.

---

value will rise), this error does not substantially affect the argument. If rights owners had no alternative but to lease their rights, the rent would necessarily equal the depletion allowance only in the case where it would otherwise be zero. The prospective  $\frac{1}{8}$  is, as Davidson points out, not the only incentive a rights owner has for leasing—bonuses and per acre rentals are usual and sometimes substantial in amounts. Claim owners are also permitted to apply percentage depletion to their royalty payments.

The coincidental nature of the current equivalence of the two figures is made even more obvious by the fact that the "value" of the depletion allowance is much higher now than it was in 1939, but the basic 12.5 per cent producing royalty has remained unchanged. With the tax rate on corporate incomes above \$25,000 set at 19 per cent in 1939, the "value" of the depletion allowance was then a little over 5 per cent.

<sup>3</sup> This is not to imply that the number of feet drilled per barrel found is the only relevant cost variable. It is the largest single item and accounts for about 70 per cent of the nonlease cost of finding new fields [7, p. 551]. The existence of other cost items that do not vary in the same manner from area to area may change the relative area rankings, not the principle. It should be noted that there are three phases involved in the "production" of new crude oil reserves: geological and geophysical activity, exploratory drilling, and development drilling. For simplicity, we might consider a new field to be "found" when a successful oil well first comes into being. The evaluative ranking procedure outlined above is relevant to all three phases, although only very rarely will a new field not appear to be worth development or at least further exploratory drilling. Leases are generally obtained after some geological and perhaps geophysical evaluation of the prospects, and always before exploratory drilling takes place.

It is clear that the appropriate model is that of the rent of nonhomogeneous land, provided that the land-using industry can be categorized fairly as purely competitive. While oil production activities are generally cartelized by state prorationing and protected by federal import quotas, the industry does appear to be substantially competitive in its exploration and leasing activities,<sup>4</sup> and the model therefore applies. Given the level of knowledge and the price of oil, the industry will rent and explore those acres that are within the extensive margin of exploration.<sup>5</sup> The purely competitive phase of the industry will earn only a normal return, plus a risk premium. All possessors of mineral rights within the extensive margin (largely the same companies in their role as oil producers) will receive rent. Those on and beyond the margin will receive none. If the expected return rises or a depletion allowance is granted, the extensive margin will move outward, more exploratory work will be done, and additional proven reserves will in all probability be added to the nation's stock. Rents on the intramarginal land will rise, and those who can appropriate them will receive them. The relative increases in total rents and in new reserves discovered will depend on the elasticity of supply of new reserves; this elasticity of supply will be zero only when every drop of oil which can be found has been found.

The strict version of Davidson's conclusion—that a subsidy will not increase exploration at all—is demonstrably erroneous. But the box remains empty; if the supply curve of new reserves is virtually vertical in the current range, then his policy conclusion remains substantially undamaged. The available evidence does not permit derivation of a full-scale statistical cost curve of a convincing nature, but certain data are suggestive.

1. *Undiscovered Reserves and the Supply Curve.* Netschert [9] presents the results of 10 estimates of the total "ultimate" crude oil reserves of the United States, all made between 1948 and 1960.<sup>6</sup> These estimates range from 140 billion to 2,000 billion barrels; the median estimate is 200 billion. Since past production plus known reserves as of December 31, 1960 amounted to approximately 96 billion barrels, it would appear that about half of the crude oil which could be produced with current technology and costs remains to be found [3, p. 47].<sup>7</sup>

<sup>4</sup> See [7, p. 571]. These government activities affect the value of newly discovered reserves, and therefore the amount of exploration, but do not alter the competitiveness of the activities involved in finding the new reserves.

<sup>5</sup> In 1960 about 19 per cent of the area of the United States was under lease [3, p. 59]. It should be emphasized that the acquisition of more information or technological change can shift areas from one side of the margin to the other—and even back again.

<sup>6</sup> Netschert distinguishes between the "resource base" and "ultimate reserves." The "resource base" includes every drop of oil that existed when Drake sank the first well in 1858. "Ultimate reserves," in this context, include only the portion of the resource base that was or is recoverable with current technology and costs. "Ultimate reserves," then, are the sum of all oil produced to date, the American Petroleum Institute estimate of "proven reserves," and the amount of undiscovered oil that could be made available with current costs and technology. It does not include shale oil, which is apparently currently close to the margin [9, pp. 295-300, 397].

<sup>7</sup> It should be noted that production plus proven reserves have already exceeded some previous estimates of ultimate reserves. It is entirely possible that the 200 billion figure will also prove to be too low.

It is impossible to specify properly the percentage of the potentially oil-bearing land which has been explored, for the term is relative not absolute. An industry committee report, however, estimated in 1952 that production was current on only about one per cent of the 80 per cent of all U.S. territory that is potentially oil and gas bearing [8, pp. 45-46]. It is further estimated that, at the then current rate of exploratory<sup>8</sup> drilling, it would take 50 years to drill exploratory wells to an average density of one per three square miles [8, p. 56]. Since it has been not infrequently necessary to drill to greater density in order to find the oil pools which existed, even that figure would in no sense represent full exploration. That the supply curve of new reserves is not vertical is hardly open to question; new reserves are being added each year.

These reserves, when found, could presumably be extracted at roughly the current cost level [9, p. 348], but this does not imply that they can be found at the current finding cost level. There is some historical evidence to indicate that the static supply curve of new reserves may have a substantial upward slope. Data for the period 1944-60 show virtually no change in the percentage of new-field wildcats that find oil or gas [1, p. 714].<sup>9</sup> New field wildcats are, however, gradually increasing in depth [1, p. 709],<sup>10</sup> and there appears to have been some tendency for the average size of fields found to diminish from 1946 to 1954.<sup>11</sup> Even without taking into account the increased volume of geological and geophysical work, which is largely responsible for the stable percentage of wildcats that find oil or gas, it would appear that it has been getting harder, in real terms, to find an extra barrel of reserves. The static real supply curve probably has had a substantial upward slope, but its elasticity was probably considerably greater than zero, for cumulative discovered reserves nearly doubled in the period 1944-60.<sup>12</sup>

2. *Statics, Dynamics, and Policy.* In the absence of a vertical (or virtually vertical) static supply curve, Davidson's argument fails to apply. Increasing

<sup>8</sup> "Exploratory" wells are customarily divided into two subclasses, those on structures which are not yet producing, and those on already producing structures. The former are referred to as "new field wildcat" exploratory wells [1, p. 703]. The statement above is apparently based on the broader concept. Elsewhere, I have used "exploratory" to mean "new field wildcat," and "exploration" to refer to the search for new fields. Fields are made up of one or more pools.

<sup>9</sup> The average for the period is 11.08 per cent.

<sup>10</sup> The increase is fairly regular from an average of 4,203 feet in 1944-46 to 4,956 feet in 1958-60. Cost per foot increases with depth, so constant dollar costs rose more rapidly than the footage figure alone would indicate [3, p. 21].

<sup>11</sup> The annual review of exploratory drilling in the *Bulletin* of the American Association of Petroleum Geologists gives estimates of the number of fields found in each of several size classes on an annual basis. Evaluation of the size of fields is exceptionally difficult until a few years of development drilling have provided fuller data on their size and contents. The statement above is based on evaluation of the number of fields in each of the size classes six years after the discovery year. The percentage of new oil fields which after six years are either abandoned or estimated to contain less than 1 million barrels of crude oil has risen from 73.3 per cent in 1946-48 to 79.6 per cent in 1952-54. Calculated from [1, 1952-60, June issues].

<sup>12</sup> Cumulative discovered reserves rose from 50 billion barrels in 1944 to 79 billion in 1954 and reached 96 billion in 1960 [2, p. 62] [3, p. 46].

the subsidy will induce further exploration, and more rapid additions to proven reserves. The extra amount of exploration and reserves would appear to depend on the actual slope of the cost curve discussed above, but this is not so. The search for oil has witnessed a substantial amount of technological change, and is likely to witness more. Since the impact of this technological change has been to push the supply curve to the right, the fact is that, even if the static curve were to be fully delineated, it would not provide a sound basis for policy formation. If a change in the subsidy rate affects the flow of innovations in the industry, as would seem likely on a priori grounds, then the static curve loses almost all its relevance for policy formation—any subsidy policy will change the static curve on which the policy is based. If changes in the subsidy rate had no effect on technological change in the industry, the static curve would shift in response to exogenously determined technological changes. In this case the ratio of the increment in total subsidy payments to the increment in reserves caused thereby could not be determined by simply examining the static supply curve, and the social cost of the policy could not be determined. In both cases the moral is clear: policy cannot properly be formulated in the absence of a knowledge of dynamic as well as static elements.<sup>13</sup>

## Public Policy Problems of the Domestic Crude Oil Industry: Comment

In the March, 1963 issue of this *Review*, Paul Davidson developed a model of the domestic crude oil industry and attempted to evaluate certain policy matters in the light of his model [2]. Three of his more important conclusions relate to conservation, the price of crude oil, and the relationship between percentage depletion and exploration. The paper as a whole is an interesting and worth-while endeavor to apply economic analysis to such policy problems. Unfortunately, these issues are extremely complex, and in my view there are a number of points at which the analysis suffers from the failure to consider certain relevant facts and from imperfections in the mode of analysis. This comment proposes to take issue with Davidson's major policy conclusions<sup>1</sup> and to suggest that a closer look at some of the facts may raise questions about the validity of his conclusions.

### I. *Conservation*

Davidson argues that compulsory field unitization would eliminate the undesirable effects of the rule of capture and would insure that lower-cost wells were operated more intensively. I do not propose to take issue with Davidson on the purely economic desirability of unitization. Indeed, under ideal conditions (small number of parties concerned, perfect knowledge of reservoir characteristics, absence of prominent structural advantages for particular operators, absence of mistrust or obstructionism, no need for compulsory implementation by state agency) unitization would be an ideal solution. But in the institutional context of the crude oil market, unitization is probably not a desirable policy recommendation. It is not strictly pertinent to criticize a pure economic analysis of present policies merely by arguing that for political reasons it will be difficult to change them. But if an economist elects additionally to make policy recommendations ("Regulation to Assert the Public Interest"), it is appropriate to suggest that the institutional difficulties of implementing a policy that is optimal when analyzed in an institutional vacuum may make an imperfect situation still more imperfect. In this section it is argued that (1) the failure of state conservation commission regulation to achieve an optimal distribution of production among wells is due more to political than to economic circumstances; (2) greater political difficulties are inherent in the implementation of unitization than in existing conservation regulations; (3) if instituted by state authorities, unitization would very likely be accompanied by prorationing to protect marginal wells and fields; (4) even with unitization, the spasmodic nature of discoveries and long-run increasing costs may still argue for the preservation of some marginal wells under certain circumstances; (5) Davidson tends to exaggerate the degree of kinship of the old rule of capture to current state conservation regulation and to overlook

<sup>1</sup> In the original version of this comment, I analyzed Davidson's depletion argument along the line presented in Duncan Campbell's accompanying comment on Davidson's paper. To avoid duplication, I need merely indicate my complete agreement with Campbell's analysis of this point.

the evolutionary tendency of such regulation toward greater economic efficiency and a closer approach to the standard of performance theoretically possible under enlightened unitization.

In the institutional context of the crude oil market, state commissions now play (and will no doubt continue to play) an important role. Efficient low-cost wells are now producing at relatively low levels precisely because a judgment has been reached by public officials that it is in the public interest to prolong the life of stripper wells. It is this judgment that must be reversed, not merely the method of regulation, if low-cost wells are to be granted a larger share of the nation's production. Otherwise, compulsory field unitization does not necessarily imply that low-cost wells will produce at the maximum profit rate. Given the actual market context, both market demand prorationing and compulsory unitization would probably come to exist side by side, if for no other reason than that compulsory unitization cannot be achieved without implementation by an agency of the state. Public officials could very well persist in their present judgment that the public interest requires production of more oil from marginal fields than would otherwise be the case. Thus, efficient low-cost fields would be cut back to make room for higher-cost marginal fields (and possibly even for marginal wells in the supramarginal fields).

Elected public officials are likely to persist in their current attitudes in view of an inherent bias in the legislative arrangements of a democratic nation in favor of small businesses, which are vastly more numerous than large ones in many industries.<sup>2</sup> The possible social benefits of such a dispensation are not at issue in the present context; it is the economic implications which are pertinent. The larger integrated producers typically produce a greater portion of their crude oil from supramarginal prorated wells than from marginal exempt wells; for the small independent producer, the reverse is true. Hence elected officials have a certain incentive to favor marginal wells when granting allowables. In the absence of such political pressure, a more rational allocation of production among wells could be achieved. But under unitization, the regulatory commission would be subjected to even greater political pressure since compulsory unitization entails much more comprehensive control, is regarded with suspicion, and is generally unpopular among producers. Individual small producers oppose unitization out of the fear that they will be unable to assert their interests in particular fields where one or more majors have large holdings. The majors are uneasy about unitization in view of the proven ability of small operators and royalty owners to organize to influence regulation and press for special legislation. The resulting pattern of regulation under unitization might be more strongly stamped with the imprint of political expediency than is the present system.

There is little doubt that the protection of stripper wells has been carried too far. But whether under prorationing or unitization, there may be valid eco-

<sup>2</sup>It is scarcely necessary to give examples, beyond a reference to the "fair trade" laws, the Robinson-Patman Act, and the laws regulating the various transport media, particularly with regard to entry policy.

nomic reasons for preserving some production from currently submarginal wells for certain periods of time. Over the long run, the petroleum-supply picture is characterized by great uncertainty in the exploration phase, with a very strong purely random influence on the level of annual discoveries. Consequently there is a chronic imbalance between current additions to supply and current levels of demand. Instead of being able to find new reserves precisely when they are needed, there is a recurrent (but not periodic) bunching of major discoveries, with intervals of sparse discoveries in between. Since the long-run supply curve seems to be characterized by increasing costs [6, Parts I and III] [4, Parts II and III], it is in many cases more costly to allow stripper wells to be abandoned (with the resulting loss of physically readily producible reserves) when supply temporarily exceeds demand at price levels necessary to maintain them in production, than it would be temporarily to curtail the output of supramarginal wells. If such marginal wells are abandoned, and if supply later declines and prices increase, it may cost more to drill entirely new wells at higher costs to replace reserves lost through prior abandonment.

To repeat: this is not to say that all prorationing practices currently in use can be justified on grounds of long-run economic efficiency. It is possible to pay too much to keep marginal oil in the supply picture, but it is also possible at times to pay too little. In 1931, as Davidson cites, the price of oil in the East Texas field fell to 10¢ per barrel. No one believed that the long-run supply curve for crude oil was at 10¢ per barrel. As a matter of public policy it was felt wise to protect marginal producers who were producing at a cost of over 10¢ per barrel. Regulation subsequently established a higher price, but submarginal wells which were not profitable even at the higher price still had to drop out. Then, with the onset of World War II, it was necessary to subsidize production, and it appeared fortunate that the abandonment of marginal wells of the 1930's had been prevented. This was not merely a wartime phenomenon, however; as late as 1948, all wells in the country were producing at approximately their maximum efficient rates of production as defined by the National Petroleum Council, in order to meet demand, even at increased prices.

Furthermore, Davidson tends to overstate the case against current conservation methods by failing to allow for the extent to which the latter have been rationalized over the years.<sup>8</sup> Hence, although Davidson concedes that prorationing diminishes the effects of the rule of capture, he fails to make clear

<sup>8</sup> Progress has taken the forms of (1) more precise measurements of MER, (2) provisions for pooling agreements, (3) arrangements (usually voluntary) for unitization, (4) a shift away from prorationing formulas emphasizing per-well allowables (which stimulate over-drilling) toward formulas emphasizing per-acre allowables, and (5) successively requiring wider and wider well-spacing. In recent years, wider well-spacing has been the general rule, particularly in the two most important oil-producing states, Texas and Louisiana. In 1962 Texas increased its minimum well-spacing regulation from one well in 20 acres to one well in 40 acres, and Louisiana increased its minimum from a former range of 18 to 40 acres per well to a requirement of 80 acres per well. See *Oil and Gas Journal*, March 12, 1962, p. 64; Oct. 8, 1962, p. 70.

the extent to which the present system is superior to the unrestricted rule of capture. It is important to understand how greatly the rule of capture has been modified by the adoption of pooling agreements, field unitization, and minimum well-spacing regulations in producing states. The major cost of the old rule was in the host of unnecessary wells it caused to be drilled; well-spacing rules reduce this waste directly. In fact, no less than 26 states now have compulsory pooling statutes which require leaseholders to pool their acreage to form drilling or prorationing units meeting certain minimum standards. Of the major producing states, only California, Texas, and Kansas do not have such statutes, and bills to provide for compulsory pooling have been recently introduced in the legislatures of Texas and Kansas. There is still room for improvement, but it is improper to ignore the substantial progress that has been made. It is likely that the eventual competition of shale oil will force further rationalization of the conservation system.

That compulsory unitization is either a necessary or a sufficient condition for the achievement of efficient oil reservoir production may therefore be questioned. Under the present state conservation statutes, virtually the same results which Davidson advocates could be achieved by modifying spacing rules.<sup>4</sup> Obtaining such modifications is once again a matter of influencing the attitudes of public officials. Unless their attitudes are altered, changing the form of regulation may have no effect on its substance. But the political difficulty (and the economic cost attendant thereto) of modifying spacing rules is apparently less formidable than that of instituting compulsory unitization, as is witnessed by the cases of Texas and Louisiana, referred to above.

## II. *Crude Oil Prices*

Davidson argues further that, even if unitization could be achieved, large integrated refiners would not be willing to pay a price for crude oil which would reflect accurately the demands of consumers on grounds that a firm with a net *domestic* self-sufficiency ratio greater than 77 per cent benefits from an increase in U.S. crude oil prices relative to product prices [2, p. 99]. Some questions may, however, be raised in regard to Davidson's statistics and conclusions. He states that in 1956 there were eight firms that would clearly benefit from a rise in the price of crude without an increase in product prices, and he adds that it is these firms which "... are typically the posted price leaders in many of the major producing fields" [2, p. 99]. Davidson is referring to data on page 224 of DeChazeau and Kahn [3], but he has incorrectly used the data on the ratio of company world-wide production to world-wide refinery runs (column 6) instead of the ratio of domestic production to domestic refinery runs (column 3). It is not only contrary to Davidson's own explicit contention to use world-wide ratios, but it is also economically inappropriate since import controls (at first voluntary and then mandatory) have largely insulated the domestic price of crude oil from repercussions from

<sup>4</sup>Spacing rules may be modified directly by decreeing minimum well-spacing or indirectly by penalizing closer spacing through reduced allowables. A flexible use of well-spacing rules can eliminate overdrilling and achieve most (although probably not all) of the benefits of unitization.

changes in the foreign price structure for crude oil. Actually, in 1956 there were only four such firms with a domestic production ratio in excess of 77 per cent of domestic refinery runs. The nation's largest refiners and its principal purchasers of crude oil all had a self-sufficiency ratio below 77 per cent. The firms that might be considered the "typical posted price leaders" (Cities Service, Gulf, Phillips, Shell, Sinclair, Socony-Mobil, Standard Oil of California, Standard Oil of Indiana, Standard Oil of New Jersey, and Texaco) had domestic self-sufficiency ratios ranging from 28 to 60 per cent. Only four of the 30 largest companies (Continental Oil, Ohio Oil, Skelly, and Sunray Mid-Continent) had net domestic production in excess of 77 per cent of their domestic crude runs, and these four firms together accounted for less than 6 per cent of the nation's net production of crude oil. It is thus factually incorrect to argue that these four firms (which are among the smaller of the group) had "... a good deal of oligopsony power ..." and were "... the posted price leaders in many of the major producing fields." By 1961, the number of such firms had declined from four to only three: Continental, Ohio Oil, and Skelly<sup>6</sup> [1, p. T-49].

Upon reflection it would seem that the greatest power to influence prices is possessed by those who have no great incentive to raise prices. The very fact that a firm is 77 per cent (or more) integrated means that it purchases relatively little crude and hence its contribution to the total effective demand for crude oil which is bought and sold prior to refining is relatively minor. Firms with lesser degrees of self-sufficiency have something to lose by higher prices, but they must buy more crude, and their greater effective demand would tend to increase prices in spite of their own interests in lower prices. These latter firms are in fact the chief buyers in many important fields, as can be verified by reference to *Platt's Oilgram News Service*, where such companies are listed daily as "reference crude buyers," and their posted prices are reported. These companies include Gulf, Texaco, Humble, Shell, Sinclair, Standard Oil of California, Standard Oil of Indiana, Cities Service, Phillips, and Socony-Mobil. Davidson's analysis also assumes that these companies can set the prices of refined products in complete disregard of the role of independent refiners and marketers, a growing segment of the market. Davidson's conclusion [2, p. 99] that "... in regional markets where there is a good deal of oligopsony power, the oligopsonists may have a vested interest in a high crude price [relative to product prices]" is simply not supported by the evidence.

Davidson realizes that a firm with a lower self-sufficiency ratio will benefit from crude price increases if product prices may also be increased. But his conclusion that "increased earnings due to product price increases are quickly

<sup>6</sup> By 1961 the separation of world and domestic crude oil markets had been made even more distinct by virtue of the institution of mandatory import controls in 1958. (Prior to 1958 the importing companies, under pressure from domestic producers, had individually exercised voluntary limitation of imports.) Mandatory import controls tended to favor the smaller refiners relative to the larger, in that allowable imports relative to refinery runs range from 12 per cent for smaller refiners down to about 8 per cent for larger refiners. Even allowing for permissible imports, none of the major integrated companies attain a 77 per cent self-sufficiency ratio.

passed down the integrated chain to the tax-sheltered production segment . . ." [2, p. 99] is open to serious question. As McKie has shown [5], entry is particularly free in crude oil production. Given such free entry, in the long run it is not possible to increase unit profit margins in crude oil production by raising prices. Any such price increases will lead to new entry and a restoration of equilibrium profit margins through the price reductions consequent upon increases in supply relative to demand.

It is also incorrect to argue that the major integrated producer-refiners have a great incentive to raise crude oil prices and increase total profits because of the inelasticity of demand. While it is true that the total demand curve for crude oil is markedly inelastic, the demand curve as seen by the typical major integrated company is apt to be much less inelastic. This comes about because the major integrated company is typically producing the bulk of its oil from supramarginal prorated wells while the small independent more often produces most of his oil from stripper wells exempt from prorationing. Since total demand is not perfectly inelastic, an increase in price will cut output, but all of the decrease in output would fall upon production from prorated wells, hence making demand much more elastic for such wells. That the quantitative increase in elasticity of demand is appreciable is evident from the fact that about 40 per cent of all production in Texas is exempt from prorationing. Therefore, depending upon the actual elasticity of demand and the majors' share in total and in prorated output, the major integrated firms might do themselves a disservice, and in any event would confer a relative benefit upon the small independent producers at their own expense, if they increased crude oil prices and thus raised the prices received by all crude producers, absorbing almost all of the impact of reduction in volume sold while leaving the sales of their smaller competitors virtually unchanged.

Davidson also argues that because of crude oil "trading" there is a built-in rigidity in crude prices since each refiner wants to prevent a decline in the price of the crude he "controls" [2, p. 100]. This argument is faulty in that it considers only one side of the market. Crude oil prices are generally determined on a field-by-field basis. The company which is a net purchaser on balance in a field will be interested in lower prices while the firm which is a net seller will desire higher prices. Since there must be a buyer for each seller, it would be more reasonable to suppose that the two opposing forces are more or less in balance, and that the secondary market for crude oil is essentially neutral in its effect on prices, except insofar as it reduces costs by eliminating cross-hauling and by channeling specific grades of crude oil to those refineries which can best utilize them.

### Public Policy Problems of the Domestic Crude Oil Industry: A Reply

In this reply, most of the space will be devoted to a discussion of Campbell's comment, for it indicates the necessity to elaborate some points of my article, and it requires further discussion about the rate of exploration. Steele's comment, on the other hand, is primarily based on what he believes to be the relevant political, rather than economic, considerations. His argument lacks analytical rigor and is, in fact, devoid of analytical content. (Moreover, his attempt to demonstrate "imperfections in the mode of analysis [of my paper]" suffers from logical errors.) Given the space limitations, therefore, I will give only brief consideration to some of the major deficiencies in Steele's argument at the end.

#### I. Reply to Campbell

Campbell has raised two issues: (1) the elasticity of supply of oil lands and its relation to the extensive margin, and (2) the effect of uncertainty on contractual rent payments.<sup>1</sup> Space limitations in my article allowed me to mention these issues only obliquely and I am grateful for the opportunity now to elaborate on them.

Campbell has set up a straw man only dimly related to my model. He proceeds to "completely vitiate" the "strict version [straw man] of Davidson's conclusion—that a subsidy will not increase exploration at all." This is not an accurate interpretation of my position, for I have stated that "percentage depletion does not *significantly* encourage the allocation of additional resources to exploring presently nonproductive oil lands . . . [it] is *primarily* an ad valorem subsidy to mineral rights owners" [3, p. 107, italics added; also see pp. 102]. In other words, the present depletion policy is an inefficacious means for encouraging the allocation of additional resources into the exploration of oil lands.<sup>2</sup>

<sup>1</sup> Campbell, however, misses the significance of the latter point, that is, that with lease contracts and uncertainty, actual rent payments to landowners (which are based on *ex ante* rents) need not equal *ex post* rents.

<sup>2</sup> Inefficacious in the sense that most of the subsidy dollar goes to windfall rents and very little remains to encourage producers to explore.

Having demonstrated that the straw man's (but not my) conclusion is wrong, Campbell implies that the opposite inference must be true, i.e., that the depletion allowance will significantly encourage exploration. To buttress this vulnerable position, Campbell introduces three items: (1) a passage from "the most authoritative academic students of the industry," who, it turns out, are merely citing works of others; (2) a visceral belief, without justification, that the depletion allowance "affects the flow of innovations in the industry"; and (3) some statistics on oil reserves which are meant to be "suggestive" of the elasticity of oil lands.

None of these items analytically advances Campbell's position. His appeal to authority as well as his visceral beliefs are extraneous. Thus, all that remains to be disposed of are the statistics on oil reserves.

Before turning to an analysis of this issue, it will be useful to present a brief list of the areas of agreement between Campbell and myself, followed by a list of areas of disagreement. The areas of agreement are:

1. Campbell apparently agrees with my analysis of the problem of conservation [3, pp. 85-101], including the analysis of crude oil prime costs such as operating costs, user costs, and royalties. Furthermore, he appears to accept the notion that, although royalties are an important component of the short-run supply function, they are, in the long run, price determined.

2. He apparently accepts the analysis on the "Crude Oil Buyer" which demonstrates that, in the short run, percentage depletion gives many integrated refiners a vested interest in higher crude oil prices and as a result tends to distort short-run production decisions from the social optimum [3, pp. 98-101]. Thus, Campbell must agree that, given the integrated structure of the domestic industry, percentage depletion is an undesirable public policy from a short-run viewpoint.

3. Campbell explicitly states his agreement that mineral rights owners normally receive economic rents.

The areas where Campbell and I disagree are the following:

1. He states that "the critical assumption underlying Davidson's conclusion is that the supply of new oil land is perfectly (or nearly perfectly) inelastic . . . [and] assuming homogeneity, Davidson's argument then follows nicely." But I never assumed homogeneity! Campbell apparently leaped to this erroneous conclusion by missing the relevance of my statement that "the landowner of any undeveloped oil property exhibits a perfectly inelastic supply function for his mineral rights—there is no alternative use" [3, p. 104]. In my discussion of the incidence of a reduction in the depletion allowance, the reference to the individual landowner's inelasticity of supply merely indicates that any payment to the landowner is an economic rent which can be taxed away without any resulting allocative effects.

Oil lands are obviously analogous to the Ricardian case of agricultural lands of differing fertilities, and I shall show below that the policy conclusion of my article is completely consistent with this fact.<sup>8</sup>

<sup>8</sup> The similarities between the differential fertilities case and the homogeneous land case have been so ubiquitously developed in the literature that I felt little compulsion to elaborate on this point. Campbell has indicated that I should have.

2. In his second footnote, Campbell implies that I believe that the royalty rate must always equal the after-tax value of the depletion allowance on corporate income. This is quite surprising since in the same footnote Campbell states "... as Davidson points out, [royalties are] not the only incentive a rights owner has for leasing—bonuses and per acre rentals are usual and sometimes substantial in amount." Since economic rent payments to landowners can take several concomitant forms, while the depletion allowance is not the sole source of economic rents, it should not be surprising to find that the royalty rate does not necessarily exactly equal the economic rent arising from percentage depletion. Campbell's apparent failure to comprehend the role of uncertainty in the determination of contractual commitments to pay economic rents leads him to place too much emphasis on my arithmetic illustration which explicitly assumed perfect foreknowledge [3, p. 104, n. 21].

#### A. *Uncertainty and Economic Rents*<sup>4</sup>

Uncertainty about the future is the critical part of most investment and production decisions. Normally we abstract from uncertainty by postulating a certainty equivalent.<sup>5</sup> As I have already indicated, if the future income stream of each oil-bearing property is known with certainty, then the lease bonus would exactly equal the discounted value of the future economic rents on the property, and all rents would go to the landowner. There would be no need for royalties [3, p. 104].

Often, when purchasing a capital asset, the estimated future income stream is known with such a high degree of probability that the buyer and seller can agree on a fixed purchase sum which each feels approximates the *ex post* economic rent. This is not, however, true of oil leases. Given the large dispersion around the expected mean value of an oil property (the probability of an extreme result such as a dry hole or a gusher is significant), both the producer and the mineral rights owner recognize that the probability of the *ex ante* rent even approximating the *ex post* economic rent is extremely small. Consequently, a royalty payment based on a percentage of the gross value of crude oil as it is produced allows the producer and the landowner to share in the inherent risks. The way the parties contractually agree to split the expected economic rent into a fixed sum (the lease bonus) and a variable sum (the royalty) depends, in part, upon the expected risks for different classes of oil-bearing properties. As one expert in petroleum engineering described the process:

If the land is remote . . . and the presence of oil beneath the tract is uncertain, the owner may have to be content with a small royalty . . .

<sup>4</sup>For an excellent discussion of this whole question see [8, Ch. 9].

<sup>5</sup>For example:

An entrepreneur, who has reached a practical decision to his scale of production, does not, of course, entertain a single undoubting expectation of what the sale-proceeds of a given output will be, but several hypothetical expectations held with varying degrees of probability and definiteness. By his expectations of proceeds I mean, therefore, that expectation of proceeds which, if it were held with certainty, would lead to the same behavior as does the bundle of vague and more various possibilities which actually make up his state of expectation when he reaches his decision [4, p. 24 n. 3].

[and] without any cash consideration or bonus. If the land is near productive acreage and the structural conditions seem favorable, the owner may demand an initial payment or bonus in addition to a substantial royalty. Some owners prefer to have a large initial bonus and a small percentage . . . while others will be willing to share the risks, and receive a smaller bonus, or none at all, in return for a larger royalty. Generally, the lessee prefers to offer a higher royalty in lieu of a large bonus, as this arrangement reduces the preliminary outlay that is sacrificed in the case the property becomes nonproductive [9, p. 169].

Accordingly, in a world of uncertainty, there is no guarantee that the royalty rate must equal the after-tax value of the depletion allowance.<sup>6</sup>

Since once oil is discovered, the lease contract normally remains in force as long as oil can profitably be produced, if the landowner has (from hindsight) made a bad deal, the producer will end up with some of the *ex post* economic rent. On the other hand, if the producer's expectation proves to be too optimistic, then in the short run the landowner might receive more than the *ex post* rent. Since, in the latter case, the producer will earn less than a normal return on his investment, it will not pay him to develop the property under the existing contract. Thus, statistical data on actual rent payments to mineral rights owners (such as the data introduced in the next section) are likely to *underestimate* the *ex post* economic rent on producing properties, because only that property on which, under existing contracts, the landowner receives less than or, at most, an amount equal to the *ex post* economic rent will be developed and remain in the statistical series.

The key point is that, given uncertainty, the depletion allowance merely raises both the landowners' and producers' estimates of the *ex ante* rent. There is no reason to believe that this subsidy will systematically increase the amount of the *ex post* rent that the producers receive as compared to the amount the producers might receive in the absence of the depletion allowance, and therefore it should not significantly encourage additional exploration of oil lands.<sup>7</sup>

<sup>6</sup> The actual contractual agreement on the mode of making rent payments to the landowner depends on a number of factors, including expectations about the future income stream, the subjective estimates of the risks involved, the risk-aversion functions of the landowner and the producer, and the ability of the producer to obtain financing. The popularity of the  $\frac{3}{8}$ th royalty might be partly explained as an institutional rule-of-thumb, for experience has shown that a  $\frac{3}{8}$ th royalty takes about half of the revenue that remains after paying all operating expenses "in the average case" [9, p. 170].

<sup>7</sup> If the producers had better information about prospective yields than landowners, and if there were collusion among producers in their bidding for leases, then the producers could systematically keep some part of the *ex ante* rent for themselves by making favorable contracts. If this collusion exists (and both Campbell and I agree that it probably does not exist in the domestic market), a reduction in the depletion allowance would tend to bring about a reduction in collusive bids. The producers could still obtain a share of the *ex ante* rent, while passing the entire burden of the tax back to the landowner. Of course, to the extent that producers were obtaining a share of the rent, then this portion of the producers' income could be taxed away without altering allocative decisions.

### B. *The Inelasticity of Supply and the Extensive Margin*

Since oil lands are not homogeneous in their oil-bearing potential, Campbell is ultimately driven back to examine the question I originally raised—that of the elasticity of supply of oil lands, for “the more inelastic the supply of mineral lands, the greater will be the landowners’ windfalls, while the additional exploratory activity will be minor” [3, p. 102]. If these windfalls are large, then (1) the depletion allowance is primarily a subsidy to mineral rights owners, and consequently (2) the present depletion policy is an exceedingly expensive (for the taxpayers) way to encourage additional exploration, and (3) my initial conclusion about the efficacy of the present depletion allowance remains undamaged.

Campbell presents some statistics on oil reserves which he claims “are suggestive”; but these figures actually do not have any direct relationship to the relevant elasticity. For example, Netschert’s estimate on “ultimate reserves” only indicates an external constraint to the supply schedule and states nothing about the elasticity of supply.<sup>8</sup> Furthermore, the fact that cumulative proved reserves “nearly doubled in the period 1944-60” has no relevancy to the elasticity of supply of oil lands, and although Campbell argues that it is “suggestive,” he does not show any connection between proved reserves and the relevant elasticity.

The development of proved reserves is really a “shelf-inventory” problem and has no direct relationship to exploration of presently nonproductive oil lands. In a forthcoming essay, M. A. Adelman has an excellent and thorough discussion of this shelf-inventory point [1]. For my purposes here, it is sufficient to indicate that Adelman is able to set up analytically a classificatory scheme in which discovered, but yet underdeveloped, oil fields are considered to be raw material inventory, while reservoirs under development are work-in-process inventory, and fully developed fields (i.e., proved reserves) are merely shelf-inventory.

The level of shelf-inventory is, of course, primarily a function of expected sales, and since sales have continued to increase since 1944, it is not surprising to find “cumulative [proved] reserves nearly doubled during the period.” Statistics on the development of shelf-inventory do little to clarify the question of the elasticity of supply of nonhomogeneous oil lands.

Fortunately, however, there are other data which enable us to judge the elasticity of supply. If the supply of nonhomogeneous oil lands is very elastic, then the rent on intramarginal oil lands will be quite small, while if the supply is quite inelastic, then intramarginal lands will yield large *ex post* economic rents. Bain has provided some estimates of actual rent payments received by owners of producing (intramarginal) oil properties in the state of California for the period 1929-40 [2, Vol. 2, p. 84]. Bain’s data show that total rent payments to landowners over this entire period exceeded the producers’ total income by approximately 18.5 per cent (or \$96 million). Even though this

<sup>8</sup> Campbell’s footnote 7 suggests that estimates of ultimate reserves should be taken with a grain of salt.

estimate is, as suggested above, biased downward, it is apparent that huge economic rents are earned on intramarginal lands. It follows therefore that the supply of nonhomogeneous oil lands is highly inelastic and that percentage depletion added substantially to the huge windfalls received by landowners.<sup>9</sup> Accordingly, for each dollar of subsidy granted, most went to intramarginal rents, and little was left to encourage the exploration of otherwise intramarginal no-rent land.

### C. *Exploration: Intramarginal vs. Inframarginal Land*

Bain's statistics provide strong support for my initial conclusion that the present depletion tax policy is an inefficient method of encouraging additional exploration. A reduction in the depletion allowances will not therefore significantly discourage exploration, although some marginal oil lands may once again become inframarginal.

As long as large areas of intramarginal oil lands remain to be explored, however, it seems unwise to encourage the exploration of any lands with inferior potential.<sup>10</sup> Moreover, we are already pursuing other public policies (prora-

<sup>9</sup> Interestingly, in another volume of his monumental study, Bain adopts an analytical argument similar to mine when he proposes an increase in the oil severance tax. Bain argues that the increased tax will have an impact on the large oil rents, including those obtained by the producer (for Bain believes that producers manage to obtain some *ex post* rent via favorable contracts). He cautions that "vigilance would have to be exercised to insure that its [the severance tax] burden is not shifted between producers and landholders through the revision of royalty terms on new leases" [2, Vol. 3, p. 60]. Bain expected a vigorous attacks on his proposal, but he argued that huge rents have occurred and the tax scheme he proposed "would recover only the unnecessary excess" [*Ibid.*, p. 60].

The fact that income received by landowners of oil properties involves huge economic rents is well recognized in oil-producing states where local tax collectors have normally assessed royalty oil at a substantially higher valuation than a barrel of producer's oil from the same well [9, p. 175].

<sup>10</sup> Campbell cites a National Petroleum Council estimate that it would take 50 years to explore all presently known potentially profitable oil-bearing lands. What determines the rate of exploration on this intramarginal land and why does so much intramarginal land remain to be explored? Many more analytical studies are needed before a definitive answer can be formulated to these questions. Some possible lines of inquiry, however, can be suggested.

Many factors contribute to the actual rate of exploration. For example, imperfections in the capital market make the financing of lease contracts and exploratory activity difficult. Also many acres of intramarginal land are already under lease and will be explored only when the lessee believes it is profitable to do so (which, in turn, depends on several factors including expected future prices and costs, i.e., the user cost of raw materials, the scarcity of geological teams and managerial ability, etc.).

From a conceptual point of view, Lerner's distinction between the marginal productivity (or efficiency) of capital and the marginal efficiency of investment [6, pp. 334 ff.] might usefully be employed to explain the rate of exploration of intramarginal land. Although Campbell is correct that "no two acres have exactly the same potential" (cannot the same statement be made for any factor of production?), there are sufficiently similar attributes so that violence is not done to reality if oil lands are divided into a relatively small number of quality classes, where the between-class variation is significantly larger than the in-class variability. We can then speak of a separate marginal efficiency of capital (in Lerner's sense) for each class of oil land. For those classes where the marginal efficiency of capital exceeds the rate of interest, investment in exploration will be going on. That class where

tioning and import quotas) which have resulted in higher crude prices and consequently have encouraged exploration of land which otherwise would have been inframarginal.<sup>11</sup> Isn't it the height of folly to continue a tax policy which attempts to push out the extensive margin even farther, while intramarginal lands remain to be explored?

Nevertheless, if it is believed that a pushing-out of the extensive margin is in the public interest, then a more efficient public policy would be to provide government support of geological research. The resulting technological improvements would move out the extensive margin (as Campbell recognizes in his footnote 5) and might at the same time reduce the rent on intramarginal lands.

## II. *Reply to Steele*

Although Steele concedes "the purely economic desirability of unitization," he nevertheless questions the "validity" [practicability?] of my conclusions on several grounds. Below I briefly discuss the most obvious deficiencies in Steele's argument.

1. Steele's defense of prorationing because of our inherent democratic bias in favor of small business is silly. Prorationing is normally defended by its advocates as primarily an instrument of conservation. Until now, no one has seriously attempted to argue that market prorationing is primarily a result of a conscious public desire to misallocate resources and redistribute income to the small crude oil producers. (Even if there is a public desire to improve the income position of the small crude producers, surely as economists we would prefer a system of lump sum taxes and subsidies that would achieve the desired distributive effects without incurring the economic wastes of prorationing.) The fact that the small producer tends to be unregulated and therefore gains the most from present prorationing arrangements is merely "a sop to practicality for it avoids the regimentation of a host of small enterprises" [3, p. 97].<sup>12</sup>

If, however, Steele wishes to defend prorationing on the basis of an "inherent bias," I might remind him that this nation also has an inherent

---

the marginal efficiency of capital equals the rate of interest will be marginal land, and all other classes will be inframarginal. The rate of exploration per period will be determined by the marginal efficiency of investment for each class. The equilibrium rate of exploration per period is that rate which adds expected new reserves from each intramarginal class up to the point where the value of the marginal input in exploration equals the expected value of the marginal addition of the capital asset.

<sup>11</sup> The rent-creating aspects of these policies have been excellently developed by Adelman [1]. Besides raising crude prices, the equity provisions of market prorationing make it more desirable to drill a marginal well than to drill a flush well. In East Texas, for example, a well that profitably produces less than 20 barrels a day will have no prorationing constraints, whereas a well which might profitably produce several hundred barrels a day could be restricted to a quota as low as six barrels a day. Under these conditions, exploration as well as production decisions are likely to be distorted.

<sup>12</sup> Similarly, present (summer, 1963) congressional discussions about exempting Mrs. Murphy's boardinghouse from pending civil rights legislation is more a result of the administrative difficulties of policing such a law than a reflection of an inherent democratic bias to allow small producers to be biased.

democratic bias for free markets, which field unitization could provide, while market prorationing does not. (Steele is wrong when he indicates that prorationing must exist side-by-side with unitization. To accept the *status quo* of prorationing as an unalterable institution is to remove any economic interest in the problem.)

2. Under prorationing, the decision to prolong the life of stripper wells does not have any economic foundation, despite Steele's suggestion that, in the absence of prorationing, stripper wells which have physically producible reserves might be abandoned when "supply temporarily exceeds demand." The possibility of physical producibility should not be the guiding criterion for continuing the use of facilities. If supply should temporarily exceed demand, then the user cost of raw materials would be the proper economic criterion for evaluating whether or not a stripper well should be abandoned;<sup>12</sup> and therefore, given unitization, this user cost will enter into rational production decisions.

Of course, in a world of uncertainty, mistakes in the foreseeing of future events may occur. Even though user-cost calculations are subject to human fallibility in predicting the course of human events (as is, of course, any method of conservation), user-cost computations under a system of unitization would supply the correct approach for husbanding oil reserves over time—a claim which cannot be made for any prorationing scheme.

3. Steele never refutes my argument that prorationing schemes do not correctly allocate oil resources over time. Nevertheless, he claims that "the present prorationing system is superior to the unrestricted rule of capture." To substantiate this, Steele would have to demonstrate that the economic cost of restricting production from low-cost supramarginal wells while allowing high-cost wells to be operated intensively (and simultaneously encouraging the drilling of new high-cost marginal wells [see footnote 11]) is less than the economic costs involved under the rule of capture.

The wastes of either of these systems manifest themselves differently, and since the domestic crude producing industry has operated throughout much of its life without compulsory production controls, and only on rare occasions were the wastes of the rule of capture as visually spectacular as the East Texas experience, it is not immediately obvious that the present system is, as Steele implies, significantly superior.

Moreover, the fact that 26 states have adopted some compulsory pooling statutes suggests that some of the alleged superiority of the present system may be a result of compulsory unitization laws rather than prorationing.

4. Steele is wrong when he suggests that "virtually the same results which Davidson advocates could be achieved by modifying [well] spacing rules." (Does this statement imply that Steele really agrees with the policy implications of my analysis, despite his protestations?) Well-spacing rules do *not* provide any economic guideline to the optimum rate of extraction of crude from a reservoir, while, as my analysis has demonstrated, profit-maximization

<sup>12</sup> For an excellent discussion of this point see Keynes' analysis of the carrying costs of redundant stocks in extractive industries in [5, Ch. 29] and [4, pp. 70-71].

decisions under unitization will result in the optimum rate of extraction over time.

To the extent that well-spacing rules are effective, they merely limit the economic wastes of overdrilling. Under unitization, however, only the minimum number of wells necessary to drain a reservoir economically would be drilled, and, therefore, well-spacing rules would be unnecessary.<sup>14</sup>

5. Steele's suggestion that I had "incorrectly used" statistics on domestic self-sufficiency ratios is itself erroneous. My information was not taken from the secondary source suggested by Steele, but was obtained from the industry periodical *World Oil* (June 1957, p. 101), which showed that there were eight refiners who had domestic self-sufficiency ratios that were greater than 77 per cent.

Furthermore, Steele doth protest too much when he indicates that the world-wide self-sufficiency ratios are not relevant. To the extent that refiners use their foreign crude to supplement their domestic crude supply, the domestic self-sufficiency ratio overstates the refiner's dependence on market purchases of crude. Accordingly, many more refiners will have self-sufficiency ratios (including foreign production) which exceed 77 per cent and will, therefore, have a vested interest in a higher short-run price of crude (both domestically and abroad). For example, Manes has shown that in 1962 eleven major refiners producing more than half of the total domestic output of refined products had over-all self-sufficiency ratios that equalled or exceeded 77 per cent. Manes correctly concludes that "where more than 50 per cent of the industry on both the buying and selling side of the market for the raw material has a vested interest in higher prices it is not unreasonable to conclude that industry and price leadership has been exercised in this direction" [7, p. 106].

6. Although Steele agrees that firms with lower self-sufficiency ratios will also benefit from a crude price increase which occurs concomitantly with product price increases,<sup>15</sup> he questions my conclusion that, in the short run, "increased earnings . . . are quickly passed down the integrated chain to the tax-sheltered production segment" [3, p. 99]. Despite the price data cited in my article, Steele rejects my argument because, "in the long run, it is not possible to increase unit profit margins . . . by *raising* prices" since this will encourage entry and restore "equilibrium profit margins through . . . price *reductions*" (italics mine).

Steele's position is obviously wrong, for he has mixed short-run and long-run factors. To argue, as Steele does, that short-run prices can never rise because if they do, in the long run they will fall, is logically indefensible. Once Steele admits that short-run prices can rise, then he implicitly accepts my position.

At this point, little would be gained by continuing the discussion of the

<sup>14</sup> The recent scandals about slant-drilling in Texas indicate that the equity provisions of market prorationing may actually encourage wasteful (and illegal) drilling.

<sup>15</sup> In 1956, for example, only two out of the top 31 refiners had a domestic self-sufficiency ratio below 37.5 per cent.

many other errors remaining in Steele's paper. For example, (1) he demonstrates that the demand facing prorated wells is less *inelastic* than total demand, but he concludes that it is "much more elastic"; or (2) in discussing crude oil trading, he implicitly denies that, in any field, the major purchaser from that field may be an integrated refiner who is also a major producer in that field, and therefore the buyer will not have a desire for a lower field price. The abundance of faults in Steele's Comment makes a constructive discussion between us of these vital policy problems impossible.

#### An Econometric Analysis of Population Growth: Comment

In a recent article in this *Review*, Professor Irma Adelman took issue with a possibility that I mentioned in the appendix to Chapter 10 of my *Economic Backwardness and Economic Growth*, namely that, if investment rises and consumption falls, *other things equal*, mortality rates may rise with per capita income [2, p. 173]. The language used in the paragraph in question indicates that this is a tentative exploration of a theoretical possibility and not the assertion of a universal generalization. Mrs. Adelman appears to interpret my statement as a universal generalization. However, her study does not refute the *possibility* that the relation may hold for some countries under some circumstances.

Mrs. Adelman's regressions give a negative partial correlation between the rate of growth of real per capita income and death rates. She alleges that this finding is "in direct conflict" with my theory. However, this is

not so. She set out to explain mortality rates of different age groups by (1) the percentage rate of growth of per capita income, (2) the percentage of labor force outside of agriculture, and (3) the number of physicians per 10,000 inhabitants. Neither consumption (per capita or otherwise) nor investment appears in her mortality regressions. Consequently, Mrs. Adelman has not tested the possibility that I mentioned.

She further states that the flaw in my "contention" is that "even though a higher rate of growth of per capita income is associated with a decrease in over-all consumption, it is also associated with an increase in the amount of consumer products accruing to the lower income groups. This decreases mortality among the laboring classes without a corresponding increase in the mortality rate of upper income groups" [1, p. 329]. I grant that this is a possibility to be placed alongside my own. The point is, though, that, despite her claim, Mrs. Adelman has tested neither one.

#### Erratum

In the article by Lowell Gallaway, "Labor Mobility, Resource Allocation, and Structural Unemployment" (*American Economic Review*, September, 1963), the exponents were omitted in the denominator of equation (5) on page 703. Thus, equation (5) should read:

$$R = \frac{\sigma^2 - \delta_0^2}{\delta_1^2 - \delta_0^2}.$$

## BOOK REVIEWS

### General Economics; Methodology

*Disarmament and the Economy.* Edited by EMILE BENOIT AND KENNETH E. BOULDING. New York: Harper and Row, 1963. Pp. x, 310. \$5.75.

*The Economic Effects of Disarmament.* Toronto: Toronto University Press; London: The Economist Intelligence Unit, 1963. Pp. xiii, 224. \$5.00.

As though to testify to the importance of, if not the necessity for, competent and painstaking studies of the probable economic impact of complete disarmament, these two books—each representing the culmination of a two-year research program—were prepared virtually simultaneously on either side of the Atlantic Ocean and were published within a few months of each other early in 1963. The signing of a limited nuclear test ban by the United States and the USSR shortly after their publication raises hopes for a termination and reversal of the arms race and adds further emphasis to the urgent need for studies of this type.

Both studies view the possibility of complete disarmament as an opportunity rather than as a cause for alarm—an opportunity to reduce taxes and to undertake useful programs with the released resources. They recognize that economic problems and dangers would exist, to be sure; but, by identifying them, by planning well in advance to cope with them, and by convincing the public of the necessity of adopting “a forward policy for optimum adjustment,” it should be possible to cause these released resources to “contribute more effectively to the highest-priority needs of mankind,” according to Professor Benoit in the last sentence of *Disarmament and the Economy*.

Of the two books, *Disarmament and the Economy* will almost certainly have the greater appeal for an American audience. It is the most comprehensive study of this particular aspect of disarmament yet to appear.<sup>1</sup> Except for Benoit, who directed the project and authored three chapters, or about one-quarter of the book, each of its 15 chapters was written by a different author or pair of authors—recognized authorities in their fields, e.g., Seymour Melman on the cost of inspection, Wassily Leontiff and Marvin Hoffenberg on the application of input-output analysis, Daniel Suits on econometric analysis, and Richard Nelson on research and development. This makes for broad and interesting coverage. It also inevitably results in some repetition and lack of agreement on various points (although all start from a common and agreed-upon set of assumptions), and opens up lines of inquiry calling for further research. Almost any of the chapters could be expanded into a book of its own. This may leave the reader slightly up in the air, but it is also bound to be stimulating and provocative. It would be misleading to suggest that pat answers could be provided for the complex problems raised.

<sup>1</sup>For example, the monumental *Arms Control, Disarmament, and National Security*, edited by Donald G. Brennan and published in 1961, devoted only one 11-page chapter of its 475 pages to “Economic Implications of Arms Control,” by Kenneth Boulding.

It is Emile Benoit who gives continuity to the book: in Chapter 2 he defines and describes the disarmament model which is basic to the entire study—one of “general and complete,” multilateral disarmament, “broadly consistent with the U.S. outline . . . presented at Geneva in 1962.” He translates this politico-military model into an economic model. In Chapter 12 he outlines various “high-priority” alternative uses which total altogether twice the estimated resources that would be released by the postulated disarmament. The problem as he sees it is not so much one of finding important alternative uses of released resources as it is one of adopting the proper monetary and fiscal policies “to endow the chosen programs with enough purchasing power to make them effectively able to bid for and absorb the released resources.” This in turn is his subject for the final chapter of the book, in which he examines seven alternative fiscal programs for adjusting to the assumed \$32 billion defense cut and selects one of them as the preferred solution: the “Balanced Stabilization Offsets Program” with tax cuts about equal to new government expenditure programs.

The other chapters of *Disarmament and the Economy* add flesh to this skeleton. Particular attention is given to presenting various economic “tools” for analyzing the impact of disarmament on production, on research and development, and on employment. These for the most part take the form of models of one type or another: an interindustry model, an econometric model, and a set of five models—(1) tax-cut, (2) debt-cut, (3) federal spending offset, (4) combination, and (5) a “judgment” model.

The British work, *The Economic Effects of Disarmament*, differs from the U.S. study in a number of respects apart from its concern with a quite different and much smaller economy. More than half of the British book (all of Part I) is devoted to a description of “the current level of defense expenditure in the United Kingdom” as a necessary preamble to a discussion of what might happen when this level of expenditure is sharply reduced by disarmament. Part II (some 93 pages) deals with “The Transfer of Resources from Defense Expenditure.” It starts with a brief review of disarmament experience following World War II, which is found to be virtually irrelevant because of changed conditions. Four main uses to which resources released by disarmament might be put are discussed, but without any recommendation as to an “optimum” or preferred distribution. The four types of expenditures include: private consumption, investment, and government current expenditure (a) at home, and (b) abroad. The principal conclusion is that “the need to maintain expenditure is of paramount importance; revenue considerations are of a secondary nature.” There is considerably less emphasis on methodology and model building in the U.K. study than in the U.S. study and more emphasis on the presentation of statistical material, both factual and hypothetical. Both studies assumed that “it would undoubtedly be the policy of the government of the day to keep . . . industrial dislocation and unemployment . . . to a minimum” under a program of complete disarmament.

A unique feature of the British study is its finding that “there appears to be some advantage in keeping the transition period as short as possible”—

two years or less (in contrast to the twelve-year transition felt to be necessary by the Americans). Advantages of the short transition (consistently favored by the Soviets) are found to be: (1) minimize uncertainty, (2) greater psychological impact, (3) readier public acceptance while memory of the agreement is fresh, and (4) minimize wasteful use of resources.

In the U.K. study considerable attention is given to the way in which individual firms are affected by defense expenditure. Surprisingly, in order to obtain data it was necessary to send out a special questionnaire "to a selection of companies in the industries known to carry out the major part of defense work"—aircraft, armaments, electronics, shipbuilding, etc. Nor was it known which companies actually were engaged in such work—"no official information is available on this subject." Permission to send out the questionnaires was obtained from the Ministry of Defense. Of 455 companies contacted, 251 replied and 142 reported that they had defense work. The data collected have the merit of being quite up to date, mostly based on the final quarter of 1961. However, the questionnaire was very brief and the number of respondents small, particularly for use in industry-by-industry analysis (aircraft industry: 8 respondents; electronics: 44; shipbuilding: 15). In a number of instances further details as to what might be expected under disarmament were obtained by means of interviews. All of this points to a need for improved data both quantitatively and qualitatively.

In spite of shortcomings, it is encouraging to find two major studies published in 1963 devoted to analyzing the economic effects of complete disarmament and to discussing alternative ways of avoiding sharply deflationary effects. Both studies are interesting and clearly presented and should be a stimulus to much-needed further thought and study in this area.

RICHARD U. SHERMAN, JR.

*Growth, Employment & the Price Level—Intermediate Macroeconomic Measurement, Theory & Policy.* By F. V. WALKER. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. ix, 342 \$6.95.

*Macro-Economics—The Measurement, Analysis, and Control of Aggregate Economic Activity.* By T. F. DERNBURG AND D. M. McDUGALL. New York: McGraw-Hill Book Co., 1963. Pp. x, 310. \$6.95.

The name of Keynes is anathema in some circles. Despite diligent efforts to distinguish the analytical techniques from the deficit-spending policies, confusion and suspicion remain as to just what is encompassed by "Keynesian Economics." As a result, courses bearing the name of Keynes are very scarce and one publisher (not here represented) even boasts that his elementary economics book contains no mention of Keynes.

All is not lost. There is available a very competent economist called "Macro." This economist, Macro, is most versatile. He not only encompasses everything that Keynes taught, might have taught and would have denied teaching but also supplants fields that used to take an entire semester or year to teach, such as business cycles, fiscal policy, and monetary policy.

These separate fields are also, of necessity, introduced in elementary courses in economics. There, however, the aim is to teach humility. The coverage (sometimes in even briefer compass) in the upper division courses in macro-economics purports to be adequate to evaluate live policy and perhaps even turn out real, genuine policy-makers. These "macro" courses need textbooks (we assume that was the sequence), and some very able economists have produced some very able volumes to fill the need.

The two books reviewed here are among the ablest. They take us through the problems of income estimation, the theory of income determination, the theory of economic growth, the causes of business fluctuations, and the use of fiscal, monetary, and other economic policy to deal with cyclical and growth problems. They are up-to-date in their analysis and present an excellent review of the available material.

F. V. Walker provides an analytical basis for considering the problem of maintaining a rate of economic growth adequate to employ the labor force while controlling inflationary tendencies. He presents a unified theory of growth and income determination. Attractive features of the book are: (1) a critical evaluation of national income estimates; (2) a simplified but highly informative discussion of sector analysis and flow-of-funds accounts; (3) a succinct historical summary of trends and cycles in the U.S. economy; (4) a review of the currently important question of the effects of built-in stabilizers and destabilizers; (5) an incisive analysis of price-index techniques; (6) a good circular flow analysis in terms of "net leakage" and "net pumpage"; (7) summaries at the end of each chapter and bibliographies at the end of each major topic; and (8) a very readable style.

Policy recommendations are interspersed throughout the book and there is a brief concluding chapter also dealing with fiscal, monetary, and other government policies. The brevity of the treatment of important policy matters is actually a blessing in some respects: no reader would be deluded into thinking that he has been given a substitute for comprehensive courses in monetary and fiscal analysis. The limited space accorded any specific policy, however, raises the question whether more harm than good results from such treatment. In referring to the possible wider use of sales taxes, for instance, Walker says, "The drawbacks are that such taxes abridge effective consumer choice and may impede incentives to earn income" (p. 327). A fuller evaluation would involve a comparison between income and sales taxes on these and other grounds, which is after all the significant current issue.

Walker makes the statement, "Economic growth is an increase in the nation's output, which occurs both because the ability to produce rises and because this added ability is employed" (p. 2). Some economists also emphasize definitions which run in terms of output per capita (e.g., Stigler in the American Bankers Association *Symposium on Economic Growth*) and of productive efficiency rather than the aggregate output (e.g., *Federal Reserve Bulletin*, August, 1963). Walker makes an important point when he says, "It makes no sense to say or imply that the theory is right and the facts are wrong" (p. 23). One is reminded of the definition of a tragedy as a theory

killed by a fact. The statement, "Merely standing pat is a policy" (p. 191), is a useful reminder to those who think they are doing nothing by doing nothing.

The clear and simple style of the book is well illustrated in the section on Harrod's theory of economic growth. Before the reader is aware of it, he has been taken through the complex analysis and has obtained an understanding of the major concepts without having first been required to master a catalog of technical terms. On this subject and on statistical developments of the last decade the book makes a useful expository contribution. The book is intensive and thorough without attempting to be encyclopaedic.

T. F. Dernburg and D. M. McDougall present a particularly good merger of cycle and growth analysis. There is more reliance on mathematics than in the Walker book but the more frightening parts are relegated to footnotes and appendices in this edition. The major changes from the first edition are a new chapter on the relation between static and dynamic analysis; a new chapter on "demand-pull" and "cost-push" inflation and structural unemployment; and substantial revision and up-dating of several other chapters. The chapter entitled "Financing Government Expenditures," which surprisingly deals only with public debt, contains a thorough discussion of debt burden and debt management.

The book reminds us appropriately that the gross national product should not be confused with welfare: "To appreciate this point, one has but to consider that in Elysium, where there is no economic activity, gross national product is zero" (p. 45). Under existing statutes, regulations, and interpretations, moreover, the income tax would also be zero. (The income tax form contains no line on which we have to declare our psychic income—as yet.) As Elysium becomes crowded, however, the capital gains tax will undoubtedly make its appearance.

Dernburg and McDougall point out that as a result of statistical studies using American data, "many economists no longer feel that an income-leveling policy will significantly help to raise total consumption" (p. 77). We may add that a logical consequence of this may be that an income-disleveling policy would also not help significantly to reduce total consumption. This has important implications for a greater reliance on sales taxation in the federal tax system.

They state, "Not to be in favor of economic growth is as heinous a crime in our society as is hostility to dogs and little children. But is it desirable to force-feed economic growth, as many are now urging?" (p. 217). This query may be used to provoke lively discussion in the classroom. In an incentive-based economy, the provision of incentives can hardly be called "force-feeding." And as long as there is a large volume of human resources going to waste through unemployment, the provision of such incentives is amply justified. We should not tolerate unemployment merely because we fear the consequences of full employment.

The impact that "credit card living" has had or should have on the analysis of the demand for money is called to mind by the authors' tale of the

salesman planning a business trip from Chicago to New Orleans. Discussing the precautionary motive for holding cash, they tell us that the salesman "will require a certain amount of cash to pay for travel expenses. However, if he is prudent, he will take along more money than the average amount he usually requires to make transactions during such a trip" (p. 105). That was yesterday. The prudent salesman nowadays simply takes along a pocketful of credit cards in total disregard of the impact of his behavior on traditional (i.e., Keynesian!) monetary and interest theory.

If a textbook should present conflicting points of view without attempting to convince the reader of the validity of one and the invalidity of the other, there are several instances in which this book qualifies. After reading the following paragraph, one is in doubt whether or not to become upset by mild inflation:

We are not among those who feel it necessary to cry havoc each time the price level rises by a small amount. Neither are we comfortable about the "relax and enjoy it" attitude of some economists. There is always the danger that mild inflation may gradually snowball into hyperinflation. Because a steady, though minute, rise in the price level may create such expectations that people will behave in a way that makes further increases inevitable, it would be folly to take a flippant attitude toward mild inflation (p. 222).

One is also left up in the air when, after discussing expansion of investment-goods production via forced savings, the authors say, "But whereas the banks are the villains of the piece to Hayek, to Schumpeter they are the indispensable instruments of capitalist progress since it is they who make resources available to the innovating entrepreneur. Apparently, it all depends on the point of view" (p. 243). With conclusions like this, students are likely to go through life not knowing whether bankers are good guys or bad guys!

There is no fence-sitting in the concluding chapter, however, in which some very strong assertions are made about cost-push inflation and structural unemployment. The discussion there is controversial, courageous, and stimulating. The same may be said of the analysis of the relation between the level of activity and budget deficits in the chapter on fiscal policy. It provides a basis for understanding the futility of trying to balance the budget simply by balancing the budget.

Both books rely on the so-called "balanced budget theorem" to determine the effects of a balanced budget. Dernburg and McDougall reach the conclusion that a balanced budget is expansionary, and that the amount of the expansionary effect is measured by the size of the budget (pp. 87-88). Walker's discussion of equal increase in government purchases and taxes is technically correct in the limited model used (pp. 191-94), but the natural tendency of a reader to assume that the author is talking about effects of a budget that includes all government expenditures (not just purchases) and all government revenues (not just taxes) is not forestalled. The author states, "An equal increase in purchases and net taxes is not neutral but has an expansive effect, even though the government budget remains balanced" (p. 194; and

see p. 215). Walker does recognize one limiting case where, "Fiscal policy cannot increase aggregate demand and output, because each dollar borrowed or taxed by government reduces private spending in the same measure. (This is the one case where the balanced budget multiplier effect does not work)" (p. 269).

The authors of these books fail to warn the reader adequately that the "balanced budget theorem" neglects liquidity effects. In a tight capital market the restrictive impact of the taxes might partly or wholly offset the expansive impact of the purchases; and in a loose capital market, if total budgetary expenditures (including appropriations to lending agencies) are balanced by revenues, there could even be a net restrictive impact of the balanced budget as a whole. Thus a balanced budget might be expansive, restrictive or neutral in its effect on GNP, not solely expansive. The authors should not be pilloried, however, for repeating a widely propagated fallacy.

Both books can be recommended highly as textbooks in courses on macroeconomics. Either can also be used as serious reading by economists of an earlier generation who received their training before the trend to growth.

HAROLD M. SOMERS

*University of California, Los Angeles*

*The Theory of Consumer Demand: A Critical Appraisal.* By GEOFFREY P. E. CLARKSON. Englewood Cliffs, N.J.: Prentice-Hall, 1963. Pp. 152. Text, \$4.95.

Geoffrey Clarkson has written a tightly reasoned methodological polemic critical of traditional microeconomic theory. It is a book well worth reading because it neatly states the logical empiricist criticism of analytical economics. It is polemical because Clarkson accepts with little qualification the now highly controversial notion that logical theory presents the paradigm of science. Once having accepted this logical empiricist position, that all *scientific* knowledge can be built from simple atomic propositions about observables extended by deductive rules of inference, Clarkson can declare that the postulates of modern demand theory have little empirical foundation and that "theories of economics have failed to meet the standards governing empirical science."

Clarkson has ingeniously applied principles of inference well known to modern philosophers and logicians to the theory of demand. A large portion of this concise book is devoted to a lucid exposition of these familiar principles. The author makes the usual distinction between deductive rules built from axioms that have no empirical content and empirical matters to which they are applied. Scientific knowledge, then, is a system of deduced hypotheses containing mainly observational terms and capable of refutation by empirical test.

Traditional demand theory, according to Clarkson, cannot fulfill this condition of refutation. Demand theory is founded in the theory of utility, a concept incapable of being formulated so that it can be subjected to empirical test. Expressed formally in "indifference analysis" or even in the "theory

of revealed preference," the utility function cannot be identified empirically. Why is it void of empirical content? Because, according to Clarkson, *any* behavior by a choosing consumer can express his "utility function" and cannot be refuted by observables. True, utility could be made empirical if real definitions and operational interpretations were given to the basic postulates of utility (i.e. that a consumer knows his preferences, that he is consistent over any designated time, that his preferences are transitive). But in practice this is not achievable because we can never know how maximal is any particular selection or what relationship holds between a chosen set, the state of information, and the universe of possible choice. Since demand theory is derived from utility theory, it too has no empirical content, nor can it readily be made empirical unless it were possible to treat "the world as though one thing varied while everything else remained constant." Demand theory, Clarkson would argue, must have content, since it is a "theory about the behavior of consumers in the market place . . . [explaining] . . . the process by which consumers make choices among alternative commodities available to them at any one point in time." But the traditional theory merely serves as a set of theoretical concepts, which, lacking the support of empirical test, provide only "an uninterpreted theoretical structure incapable of producing explanations and predictions of economic events" and yielding mainly after-the-fact rationalizations of why an event has occurred. The economist's methodology of constructing theory from empirically untested axioms has made a large body of microeconomic theory incapable of refutation by empirical test and inapplicable to the explanation and prediction of consumer behavior.

Wherein lies the remedy? According to Clarkson, it consists in the establishment of general laws of demand based upon empirically confirmed premises. These postulates would be derived from the "direct observation of human decision-making behavior," and linked to empirical evidence provided by psychology and other behavioral sciences. Traditional theory of demand must be reduced to a more microscopic set of data and postulates, a theory of individual decision-making behavior. This theory must be founded in concrete observation, in established empirical laws, in recent researches in behavioral theory, in the simulation of individual decision-making. In short, what Clarkson proposes is that the theory of human problem solving should provide the foundations for a theory of demand and, by implication, for all of microeconomic theory.

But Clarkson's preference for a science based on only descriptively rich empirical statements is not shared by everyone. The simple classifications in his analysis may even prove misleading. The "utility function" may be neither vacuous nor verified; there are mixed entities in science with some empirical content and logical form. Some postulates determine scope, and are not to be analyzed by the calculus of propositions. Nor can one agree that the theories of utility and of demand are merely concerned with the description of consumer behavior; they are part of the total machinery of economic theory which generates propositions about welfare, trade, growth, *et al.*

The concepts of a science are highly complex and frequently not amenable to the simple judgments of "empirical" or "vacuous." Might not the reduction of economics to the direct observation of human behavior result in the creation of an infinite series of particularized descriptions rather than the general theory Clarkson hopes direct observation would introduce?

Clarkson's book has the unusual virtue of presenting a strong and well-reasoned argument for a limited point of view. In economics, he has certainly raised the level of the logical empiricist demand for strong verification principles and descriptively accurate postulates. Clarkson has written a book which ought to be read by everyone interested in the methodology of economics. It is not that his ideas are particularly original, but he has presented the empiricist position in the modern mode and in a way that is both clear and stimulating.

SHERMAN KRUPP

*Lehigh University*

**Price and Allocation Theory; Income and Employment Theory;  
Related Empirical Studies; History of Economic Thought**

*A Behavioral Theory of the Firm.* By RICHARD M. CYERT AND JAMES G. MARCH, with contributions by G. P. E. Clarkson, K. J. Cohen, W. R. Dill, E. A. Feigenbaum, E. Grunberg, C. G. Moore, P. O. Soelberg, W. H. Starbuck and O. E. Williamson. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. xii, 332. \$8.25.

This book delivers a major blow to that battered but hitherto unshaken intellectual construct, the theory of the profit-maximizing firm. Its importance derives from the fact that it presents a well-elaborated alternative theory that stands up well under the tests of both systematic and casual empiricism, rather than from any novelty in the criticisms it levels against orthodoxy. Indeed, the interpretation of the book as a challenge to orthodoxy is mainly the reviewer's rather than the authors'. The latter are, if anything, overly willing to accept the alibi that the received theory was never intended to be a theory of the how or the why of business decision-making, but only of the behavior of markets. The legitimacy of this alibi has been a matter of some dispute, but the authors forestall any corresponding disagreement about their own objectives. They are interested in developing a positive theory of the economic behavior of the individual business firm. If success in that endeavor contributes to success in predicting more macroscopic phenomena, or if it advances the normative theory of the firm or of the whole economy, that will be an instance of external economies.

The most distinctive feature of the authors' research strategy is their fundamental assumption that the positive theory of the individual firm must be *process oriented*, i.e., the theory must be a representation of the essentials of the process by which firms make decisions. Organization theory in the tradition of Barnard and Simon (and March) provides the set of concepts and some of the hypotheses that structure their view of the decision process. The elaboration of those concepts and hypotheses in the specific context of busi-

ness decision-making seems to render them a good deal more concrete (and perhaps more interesting to most economists) than in some earlier formulations.

The main elements in this view of decision processes in the firm may be summarized as follows. First, the firm is a coalition in which goal conflicts among the participants are never permanently resolved. The effective goals of the firm in any given situation are governed by the bargaining process which fixes the composition and general terms of the coalition, by the control procedures of the firm, and by the effects of experience on the aspirations and attention focus of the participants. The bargaining process at a given time is, of course, severely constrained by the precedents and policy commitments established at earlier times. Second, firm behavior is goal-seeking, not in the sense that an attempt is made to maximize some over-all utility function for the organization, but in the sense that an attempt is made to find behavior that will satisfy a number of independent aspiration level constraints. That is, *satisficing* behavior in a number of utility dimensions replaces maximizing behavior in a single utility dimension. Third, *search activity* is triggered by the appearance of a particular policy problem (failure to achieve goals), and its direction is much influenced by the symptoms and organizational locus of the problem. Search is generally limited to the "neighborhood of the current alternative," i.e., policy change in the firm is incremental. In the absence of a problem, there will be little or no search for alternatives to existing policies. Fourth, the firm reacts to uncertainty by employing *standardized decision rules* that emphasize reaction to short-run feedback rather than pursuit of long-run strategies, and by adhering to "good business practice" (a sort of implicit collusion with competitors in the interests of uncertainty avoidance). Lastly, decision rules, aspiration levels, and the rules of the search process itself are subject to adaptive change through time: Search leads to modifications in decision rules; aspiration levels adjust upward or downward according as search is rewarding or not and achievement exceeds or falls short of aspiration; search tends to take the forms and directions which have yielded success in the past.

A wide range of evidence is presented in support of this view of decision-making in the firm. Four case studies of business decisions (Chapter 4) amply document the limitations of the conventional theory of the firm as a theory of decision processes within the firm, and at the same time lend support to the hypotheses advanced by the authors. The studies illustrate, for example, the prevalence of feasibility tests of proposed actions rather than optimality tests, and the fact that agreement on firm policy among the subunits in the firm may be the result of disagreement both about goals and about the consequences of the policy.

The most impressive evidence of predictive power is undoubtedly that contained in two computer simulation studies of particular business decision problems. The first of these is a model of pricing decisions in a department store, developed by the authors and C. G. Moore (Chapter 7). The flow chart for the "mark-down pricing" portion of this computer model contains

boxes with injunctions like "Reduce price by one-half, carry down to nearest 0.85," but none of the boxes contains any reference to anything resembling the concept of elasticity of demand. This mark-down pricing program predicted, to the penny, the mark-down prices of 140 out of 159 items in a random sample of mark-down decisions made by the particular department investigated. The second computer model is a simulation of trust investment behavior developed by G. P. E. Clarkson. The data employed were derived from observation of the behavior of a particular investment trust officer in a particular bank. Again, there is little resemblance between the decision-process model and anything that would ordinarily be thought of as maximizing behavior. For example, portfolio diversification is accomplished according to the rule of thumb that all accounts must participate in at least five industries, and participation in stocks is usually limited to one per industry. The model was tested by using it to predict the trust officer's choices for four accounts not used in developing the model. The model and the trust officer agreed on the number of stocks for each account; they agreed on the choice of companies in 24 out of 29 cases, and on the size of the participation in 22 out of the 24. In short, trust officers appear to be threatened by automation.

These models provide striking support for the view that business decisions are dominated by rules of thumb and standard operating procedures—at least in the short run. They also indicate that, with the help of an electronic computer, a process-oriented theory of firm behavior can be made to yield specific and highly accurate quantitative predictions—at least if the decision process investigated is sufficiently simple and the data required for estimation of the parameters of the decision rules are available. However, the qualifications appended to the foregoing statements are important ones if the theoretical framework constructed in the early chapters is indicative of the aspirations held for the behavioral theory of the firm. The fact is that only a small portion of the theory developed in the early chapters is subjected to test by these computer simulations, except in the limited sense that the theory predicts that fairly simple rule-of-thumb decision procedures will govern behavior in the short run. For example, the performance of the models does not provide any evidence that it is useful to view the firm as a coalition. Neither do these models throw any light on the sorts of search processes that might be triggered by an important failure to achieve goals for the firm as a whole. As for the adequacy of computer simulation as the chief research tool of the behavioral theory, the evidence in the book is as suggestive of the limitations of computer techniques as of their promise. While the department store and trust-investment models are clear successes, the attempts to simulate the behavior of large oligopolistic firms (Chapters 5 and 8) appear to be in grave danger of getting bogged down in the problems of estimating a large number of parameters and devising appropriate statistical tests of simulation models when the agreement between predicted and observed behavior is not overwhelmingly persuasive.

Although the emphasis on process-oriented models with computer simu-

lation as the implementing tool is the dominant one in the book, a much different approach to the behavioral theory of the firm is also represented. In Chapter 9, O. E. Williamson proposes a model of "rational managerial behavior" that, in terms of method, is much closer to orthodox theory than it is to the decision-process analysis in the rest of the book. His procedure is to introduce a managerial utility function to replace profit as the maximand in the theory. The link to the concepts employed elsewhere in the book is provided by the choice of arguments for the utility function. These are (1) spending on "staff," including managerial salaries; (2) the difference between actual and reported profits; and (3) "discretionary spending for investment," equal to reported profits less taxes less the minimum profits required to satisfy the demands of other members of the coalition (e.g., dividend demands of stockholders). Comparative statical analysis of the maximum position yields various interesting predictions; for example, an increase in the tax rate on profits will increase output and "staff" and decrease the fraction of profits reported. The predictions of the model approach those of traditional theory when the environment of the firm is sufficiently severe.

The enormous gap in technique between Williamson's work and the computer simulations suggests the existence of a correspondingly large range of as yet uninvestigated possibilities for elaborating and testing the behavioral theory of the firm. Hopefully, the continuing search for testable implications of the theory will not be confined too strictly to the "neighborhood of the current alternatives." Also, it is to be hoped that someone will eventually accept the challenge of attempting to provide a better definition of the relationship between the behavioral theory and traditional theory than is provided by the assertion that the two theories are concerned with different problems. It is, after all, a simple matter to construct hypothetical situations in which some simple version of the behavioral theory yields predictions about *market* phenomena that differ from those of the usual perfect information version of the traditional theory. (In fact, Williamson's model provides examples.) On the other hand, the consistency of the behavioral theory with the more persuasive portion of the *empirical evidence* for the traditional theory has yet to be determined. Investigation of the relationship between the two theories will probably involve closer attention to the circumstances that determine when the profit goal is evoked and when profit aspirations adjust upward, as well as to the ways in which competition may force an approach to profit maximization by firms whose decision processes are governed in the short run by crude rule-of-thumb decision rules. If the reconciliation can be effected, the resulting theory will have to be regarded as the general theory of firm behavior and the assumption of profit maximization will have to be regarded as an approximation that is useful in a limited class of problems.

For the past several years, the research on the theory of the firm conducted at Carnegie Institute of Technology has been distinctive for the boldness of its departure from the accepted modes of economic thought on the subject. Cyert and March and their collaborators have consolidated much of

that research, and the result will be impressive even to those economists who attended carefully to the fragmentary reports as they came in. Those who have not heard the distant rumblings of the "behavioral revolution" will be surprised at the momentum it has achieved. The final verdict cannot be predicted, but this book should at least convince most economists that the revolutionaries bear watching.

*Capital and Rates of Return in Manufacturing Industries.* By GEORGE J. STIGLER. Princeton: Princeton University Press for the National Bureau of Economic Research, 1963. Pp. xiii, 229. \$5.00.

This volume has two major purposes. The first is to describe and present comprehensive new annual estimates of capital and rates of return in 3-digit manufacturing industries from 1938 to 1957. The second is to analyze these and other data to determine what insights the economist can gain from them. Since this reviewer is not competent to pass detailed judgment on a data-collection task of this sort, attention will be concentrated on the three analytical essays that form the heart of the text. My remarks concerning the data will mainly pertain to matters of presentation.

The salient characteristic of George Stigler's capital measure is its comprehensiveness. In addition to the items of fixed capital usually included in studies of firms' investment policies, he includes all items of working capital except investment in other firms. He presents some persuasive arguments for his comprehensive measure, although it is not clear why investments in other firms should be excluded from a measure that includes holdings of cash and government securities. An adequate justification for compiling the new series is that the measures compiled by Creamer, *et al.*<sup>1</sup> are not available on an annual basis. However, the two measures are not the same in years for which both are available. It would have been helpful if Stigler had given the reader a brief reconciliation of the two measures.

The three analytical essays are very stimulating indeed. Their hallmark is the ingeniousness rather than the mathematical or statistical sophistication of the procedures used.

Chapter 3 examines the classical proposition that competition tends to equalize rates of return in different industries. There is a careful discussion of the theoretical relationship between competition and rates of return and of the factors that govern the strength of the tendency. That the strength of the tendency is considerable is suggested by a number of observations on the data, including the observation that the relative dispersion of investment rates is much greater than the relative dispersion of rates of return. Stigler observes almost no differences between average rates of return in concen-

<sup>1</sup> Creamer, Dobrovolsky, and Borenstein, *Capital in Manufacturing and Mining: Its Formation and Financing*, Princeton University Press for National Bureau of Economic Research, 1960.

trated and unconcentrated industries, but substantially greater persistence through time in the rates of return in the former than in the latter group.

Chapter 4 analyzes the determinants of the rate of investment. Using data from the postwar part of his sample, Stigler concludes that changes in sales receipts are much more important than profit rates in explaining investment in book values. When deflated values are used, the roles of the two explanatory variables are interchanged, since the high correlation between book values of investment and changes in receipts is largely accounted for by the similar effect of price changes on each.

The final chapter of the book is concerned with substitution between capital and labor. The usual way to estimate the elasticity of substitution is to compare differences in the capital-labor (or output-labor) ratio at different points in space with corresponding differences in wage rates (assuming, as Stigler also does, that capital costs are the same for each observation). Stigler's procedure is to make the comparison between large and small firms rather than between different points in space. He observes that earnings per worker are usually higher in large than in small firms, and his estimates yield much higher elasticities of substitution (averaging about four) than do other estimates. But why are earnings higher in large firms? Presumably, either large firms employ higher quality labor or they have some monopsony power. The former is excluded by assumption (in other similar studies as well as in Stigler's) and, if true, would invalidate the estimates. But the latter also invalidates the estimates. If large firms have some monopsony power, it means that their factor proportions are in response to a higher marginal labor cost than is indicated by the wage rate. Therefore, the large excess of their capital-labor ratios over that for small firms is partly accounted for by the understatement of their marginal labor costs. If this line of reasoning is correct, it means that Stigler's estimates of the elasticity of substitution are too high.

This is a stimulating book and contains many suggestions and hints for further work. Some of them can be followed up by others using the data that Stigler has provided for us.

*The Johns Hopkins University*

*The Evolution of Economic Thought.* By W. E. KUHN. Cincinnati: South-Western Publishing Co., 1963. Pp. x, 451.

In the last four years at least five histories of economic ideas (Blaug, Leachman, Oser, Whittaker, and Taylor) have preceded W. E. Kuhn's entry. Nevertheless, Kuhn has succeeded in differentiating his product substantially from those of his most recent competitors. For one thing his organization is designed to parallel that of the standard introductory texts. Almost the entire first half of the volume is devoted to the development of value and distribution doctrine. A single chapter on macroeconomics, here regarded almost exclusively as the contents of Keynes' *General Theory*, follows. The final 200 pages rapidly survey monetary and banking theory, international trade, business cycle theory, public finance, and the "isms." Then, too, Kuhn segregates

biographical and historical information in a series of pounds at the end of each chapter. Close to a quarter of the text is given over to these appendices and to the questions and reading lists also appended to each chapter. Finally, Kuhn distinguishes himself from his rivals in the degree of his partisanship—to his credit, openly avowed. In Kuhn's opinion scientific economics is essentially value and distribution theory. Among value and distribution theorists, "the Austrians added more to the body of pure economic theory than any other 'school'." Accordingly the text spends 36 pages on Menger, von Wieser, and Böhm-Bawerk. The corollary of this intellectual judgment is the author's depreciation of macroeconomics which leads to the peculiar treatment of Henry Hazlitt as a major critic of Keynes, and the comparative neglect of such respected Keynesian opponents as Robertson, Viner, and Haberler.

Is the result of this organization and these preferences a usable text? On the whole the first 200 pages are good, subject to some major reservations which will be noted. Chapters 3-7 which trace value and distribution from Cournot through Robinson and Chamberlin contain a closely reasoned account of obvious benefit to serious students. But this section is seriously weakened by the opening two chapters which cover the English classical school. This is one of the places where the author's special slant creates a special difficulty. By interpreting Smith and Ricardo primarily as theorists of value and distribution, Kuhn completely misses the dynamic core of the Ricardian theory. He emphasizes this lapse by referring to Malthusian population doctrine only in his biographical appendix. Hence he loses the chance to display to his readers the model of economic change which in Ricardo rests so substantially on Malthusian population assumptions. It will be hard indeed for students to avoid the conclusion that the classicists were uninterested in economic change and economic growth.

Kuhn's handling of Marxist economics is equally questionable. Marx receives some five and one-half pages of attention in the very last chapter devoted to the "isms," separated by some hundreds of pages from the English classical economists from whom he borrowed. Kuhn ignores Marx's interesting business anticipations and models. The historical school is brushed aside with three pages. Veblen earns only biographical mention and Commons little more than that. The "associationist" socialists and the radical Ricardians are nowhere to be found.

Most dubious of all is Kuhn's handling of Keynes. Although in fairness it must be granted that Kuhn does intelligently summarize some aspects of the *General Theory*, the chapter on Keynes suffers from serious faults. The comments on page 207 can scarcely fail to leave students with the impression that if Keynes had lived he would now be opposing fiscal policy and the welfare state. It is a revelation of Kuhn's state of mind that he refers to the *General Theory* as "Keynes' treatise on value theory" (p. 208). Worse still, Kuhn says nothing of Keynes' antecedents in Swedish and Robertsonian theory. His account of the controversies which followed the publication of the *General Theory* is brief to the point of distortion. Although Kuhn disclaims any "attempt . . . to arrive at a final evaluation of Keynes' contribution to the body

of macroeconomics and his inspiration of varied econometric research," he consigns Keynes to a minor place in the history of his subject by implication, omission; and emphasis.

The chapters on specialized topics which round out the volume too frequently deteriorate into a catalogue of names and contributions to permit easy use. A random check of the index suggests the omission of a large number of names and references.

In sum, despite some quite good sections and a vigorous point of view, Kuhn ought to be used as a text only with very considerable caution.

ROBERT LEKACHMAN

*Barnard College*

*Antología del pensamiento económico-social.* Edited by JESÚS SILVA HERZOG. Mexico City: Fondo de Cultura Económica, 1963. Pp. 606. 70 pesos.

The publishers announce that this volume, which covers economic and social thought from Jean Bodin to Louis Blanc, is to be the first in a set of three. Whether or not that ambitious project is ever completed, the present book fills a large gap in Spanish textbooks. The principal works in economics published after 1850 are all available in Spanish; it was always the earlier period that gave trouble. Because of the structure of Latin American schools of economics, this anthology will rather quickly be adopted by most of them for use in their standard required course in the history of economic doctrines. It will, therefore, acquire an importance which no similar anthology published in the United States could achieve.

The work is clearly identified as a textbook, with no particular pretensions to scholarship. Several of the translations are even at one remove: those of Serra, von Hornick, von Justi, and Galiani, all of which are Spanish translations of the English translations found in Monroe's *Early Economic Thought*. Ever since the establishment of the Library of Congress' microfilm service, that sort of thing has not really been necessary. Also, the text is marred by endless typographical errors: Adam Smith's famous pension is quoted at £800; the U.S. Constitutional Convention is said to have met in 1887; the date of Babeuf's birth is given as 1706; and the like. These and hundreds of similar errors will only annoy economists but they may well mislead students.

As a textbook, an anthology of this kind has long been needed. Up to now the collections available in Spanish have either been monumental and relatively inaccessible, like Sempere y Guarinos' *Biblioteca española económico-política*, or sketchy and out of print, like Silva Herzog's own 1939 anthology. Now, building on his forty years of teaching the history of economic thought in various Mexican universities and on his earlier publications, the editor has put together a comprehensive and useful anthology. All of the standard names are present, grouped into mercantilists, transitional economists, physiocrats, classical economists, and social critics and Utopian socialists. But a number of surprises await the reader: selections from the works of Juan de Mariana, Juan Botero, Jerónimo de Uztáriz, Bernardo Ward, the Conde de Campomanes, Gaspar Melchor de Jovellanos, Álvaro Flórez

Estrada, Morelly, and Babeuf. The availability of these selections should add a note of color to future seminars.

Some of the selections made from standard authors seem a bit odd. The inclusion of such writers as Locke and Rousseau is well within the editor's self-imposed limit, but certain other extracts are dubious. For example, only the first third of Turgot's *Réflexions* is reproduced, the third in which he merely recapitulates the system of Cantillon and Quesnay before settling down to present his own contributions. The specimen from Campomanes is a letter to the Conde de Lerena in which he castigates the internal revenue in an unexceptional fashion, rather than, for example, the *Discurso sobre el fomento de la industria popular*, which so aroused McCulloch's admiration. One of the selections from Quesnay is, inevitably, the *Tableau économique*, but only the verbal exposition. The *tableau* itself is omitted, a fact which will very likely make the whole exposition unintelligible to students. And the essay chosen to represent Hume is the pedestrian one on commerce rather than the more analytical ones on interest, balance of trade, or money. But these points should not obscure the fact that the collection as a whole is first-rate: all of the necessary names are included; and, in the main, the selections are representative.

Each selection is preceded by a biographical and critical note. Instead of the brief presentations of dates and facts which are typical of United States anthologies, Silva Herzog presents the reader with extensive comments and criticisms, going on for as much as six pages at a time. The opinions set forth are such as to demonstrate the editor's *bonae fides* as a sound Latin American economist. They may not have the same effect north of the Bravo, as a few quotations might show:

It is frequently said that there never were any economists in Spain. That opinion is the result of a lack of knowledge on the part of persons who hold that opinion. All of the sciences flourished in Spain from the end of the Middle Ages and the science of Economics from the beginning of the modern period. What happened is that, since the time that Spain stopped being a first-class political and military power, she did not have and has not had the necessary might to spread the ideas of her thinkers throughout the world, as France, England, and lately the United States have had (p. 210).

I think that nowadays we know full well that the accumulation of wealth—especially great wealth—is never due to personal merit and even less to personal effort. It is due to the productive use of the energy of many persons for the benefit of one person, to the exploitation of man by man, to unbridled speculation, or to a variety of obscure, turbid, and unmentionable practices (p. 274).

Every person of even moderate education knows very well that the rich countries have exploited and are exploiting the poor countries. They know very well that the rich countries fix the prices of the raw materials which they buy from poor, underdeveloped countries, at the same time that they fix the prices of the manufactured goods which they sell. If that were not the case, then the rich countries would not be as rich as they are, nor the poor countries as poor (p. 458).

These opinions will probably pass unnoticed north of the border, where hardly anyone bothers to read editors' notes. They will be considered unexceptional south of the Bravo, where the students will study them carefully. Similarly, Silva Herzog's preliminary section, a 70-page summary of economic history from classical antiquity to the nineteenth century, will be ignored as supererogatory in the north, but read with interest to the south. The book will provide a useful addition to libraries of economics and will serve as a required text in most schools of economics in Latin America. All in all, it stands as the first substantial anthology of the history of economic thought available in Spanish.

### **Economic History; Economic Development; National Economies**

*Italy—A Study in Economic Development.* By VERA LUTZ. New York: Oxford University Press for Royal Institute of International Affairs, 1962. Pp. ix, 342. \$7.20.

In recent years, the Italian economy has begun to attract the keen interest of a growing number of outside specialists, well beyond that nation's comparative economic importance as a producer and trader. There is good reason for this.

From its inception as a national economy, Italy has developed in a curiously uneven and distorted fashion. After World War II, this gained recognition as a strong case of economic dualism, with burdensome consequences that remain large today. The postwar years were also marred by massive overt unemployment and even worse underemployment. Yet this was the very time when the great boom burst forth, giving Italy one of the highest growth rates in the world. Between 1948 and 1961, this impressive upsurge went on under quite orthodox policies toward money, convertibility, and foreign trade—in which a high savings rate, rather than a high spending multiplier, was deliberately sought. Moreover, these policies were coupled to a massive program of incentive planning for the depressed South, intended to evoke autonomous growth there by creating a variety of external economies through subsidies and public investment.

Obviously, the Italian story has needed telling, but even more, careful technical analysis. From her sustained study of the case for some 15 years, more recently as a research expert for one of the big government banks, Dr. Vera Lutz has made a substantial contribution in both respects, one that brings together and amplifies her valuable pioneering papers in this field. Considering the frustrations and sheer bafflement implicit to any outsider's use of the Italian materials, or to understanding the maze that is the Italian economy, the skill with which she cuts through to generally the right conclusions clearly puts the profession in her debt. The result is a work of much value alike to students of development, international economics, labor economics, monetary policy, and other fields as well. One could hardly find a

better demonstration of the value of undertaking factual studies after an initial mastery of economic theory itself.

The central theme of the book is that Italy was a dual economy throughout 80 years of industrial development, and remains one today—a “half-and-half system” whose dichotomies are not geographic alone, but run through particular industries and localities and even entire sectors. The North-South bifurcation is but the most obvious expression of the phenomenon. These divisions are found in techniques of production, forms of enterprise and employment, and, above all, in comparative productivities and incomes. Their explanation is complex. In oversimplified terms, it centers upon a secular shortage of capital to carry through transformation to a unified system, and a collection of misguided policies toward tariffs, wages, labor mobility, taxation, and public expenditure. The major consequence has been that the total income produced by the system for years has fallen well short of potential. No less important, particularly in the postwar years, it has enforced chronically heavy unemployment and underemployment. As Dr. Lutz herself puts it, a “common market” for labor never really emerged in Italy, and only now is beginning to appear.

The first part of her book poses her view of the Italian problem, presented through a model of a dual growth process in which the labor market plays the strategic role. Next she considers the North-South split: its nature, origins, remedies in course, and issues for policy. Taking note of the failure of the per capita income gap to close despite all efforts since 1950, she concludes that accelerated emigration north, rather than forced-draft industrialization in the South, would achieve “approximate parity” in much shorter time, and with less impairment of over-all income growth. This does not mean abandonment of the South, as its Neo-Mercantilist spokesmen have been claiming in parliamentary debates, but a shift of emphasis. In my judgment, her diagnosis is basically right, and it took a good deal of courage to voice it.

Part III then moves into a variety of special topics—agriculture, wages, the labor market, taxation, state enterprise, foreign trade, and monetary policy. All are tied together by reference to the common theme of dualism. One will find here much valuable statistical and descriptive material, all relevant to the central analysis.

In view of the distressing reversal of Italy's economic fortunes since late 1961, it is regrettable that the book mainly terminates with 1959, the more so because this was the first year in which registered unemployment finally began to show significant declines. Also disappointing is a certain lack of firmness regarding current issues, and a failure to explore more fully some highly important topics—for examples, the monetary reform of 1947, the outcome of Einaudi's monetary policy, the true extent of overt unemployment since 1952, and the main choices for policy that have been evident from the start of the 'sixties. But I do not wish to cavil. This is still the best study of the Italian economy ever to appear in English.

GEORGE H. HILDEBRAND

*Cornell University*

*The Dilemma of Mexico's Development: The Roles of the Private and Public Sectors.* By RAYMOND VERNON. Cambridge: Harvard University Press, 1963. Pp. xi, 226. \$4.95.

In this book Professor Vernon offers a perceptive, provocative prognosis of Mexico's development problems, particularly of the problem of maintaining the economic momentum which Mexico has achieved during the period since 1940. The prognosis is based on close historical study, and, indeed, one of the most remarkable attributes of the book is the clear, succinct manner in which Vernon has been able to weave together the various threads comprising the fabric of Mexican economic history. He largely eschews statistical and other conventional techniques of the economic historian and focuses instead upon interrelationships between economic and political forces.

In the first pages of the book Vernon leads his readers to expect a treatise dealing with the relative roles of the public and private sectors in the process of Mexican economic development. However, he very soon directs attention to the public sector-private sector confrontation in the political arena. This, in turn, leads to an examination of the ailments of the Mexican body politic and it is upon the results of this examination that Vernon bases his central thesis. In Vernon's view "the dilemma of Mexican development" is essentially of a political nature.

While Vernon does not undertake a detailed analysis of the strictly economic forces underlying contemporary Mexican economic difficulties, he does have a good deal to say about the nature of these difficulties. He indicates that there exists a tendency for the stimulus formerly derived from the export sector and from import-substitution policies to diminish. He suggests that there is a widespread belief among Mexican businessmen that the prospective future growth of the domestic market does not warrant expansion of productive capacity at the same rate as in the past. He argues that expansion of domestically financed public investment is circumscribed, on the one hand, by limitations on the government's ability to tax and operate public enterprises profitably and, on the other hand, by undue governmental reluctance to employ deficit financing. Neither does he foresee any great expansion of public investment supported by foreign borrowing nor any significant improvement in the quality or growth-producing stimulus of public investment—in the first instance because of the country's limited debt-servicing capacity and in the second instance because of the extent to which public investment decisions are influenced by political considerations. And finally he believes that, for political reasons, the government is unlikely to adopt policies consistent with a sharply higher rate of either domestic or foreign private investment.

Thus Vernon's prognosis is very pessimistic and indicates that Mexico presently is threatened with economic stagnation. In his own words:

In the early 1960's . . . Mexico's economy seemed to be approaching a new series of roadblocks. The country's growth appeared to be slowing a little and the prospects for some new impetus to growth seemed uncertain. If the economy were allowed to drift very long, the loss of momentum might expose the country to serious political risks and

economic losses. On the other hand, practically every major change in policy that offered some promise of stimulating the country's development also seemed to involve a considerable measure of political risk. The problem for Mexico's leaders was to find a way out of the dilemma—to seize the horn on which the country was less likely to be impaled (p. 176).

It seems clear, at least to this reviewer, that Vernon does not expect those who wield power within the Mexican political system to take the aggressive actions necessary to forestall the economic stagnation which he believes to be imminent.

Publication of Vernon's book has been anxiously awaited in Mexico not only because of anticipation that he would probe into politically sensitive matters (and just at the time activities surrounding the choice of the next president were at their height) but also because of Mexican awareness of Vernon's influence in U.S. government circles. While it is too early to gauge the over-all Mexican reaction, it must be obvious to anyone who has had an opportunity to discuss the book with Mexican readers that many are irritated by it. There is, first of all, resentment that "a foreign doctor" (as Vernon has been publicly referred to), whose knowledge of the patient's intimate circumstances is of recent origin, would presume to offer an uncomplimentary prognosis. Some Mexicans are also irritated by what they sense to be a certain disdain or condescension on Vernon's part as exemplified in his irreverent appraisal of contributions of certain national heroes (President Lopez Mateos is the object of several uncomplimentary remarks) and his somewhat derogatory use of the term "técnicos" (why not "technicians" or "economists"?). There also exists a feeling among his Mexican readers that Vernon's appraisal of the Mexican political system reveals an inability to free himself from ethnocentric, Anglo-Saxon preconceptions.

There are in addition several more substantive criticisms of Vernon's book which challenge the validity of his basic thesis. On the economic side it may be that Vernon has mistaken a cyclical decline in the growth rate for a secular trend. Furthermore, Vernon's argument seems to be premised on an exogenous or shock theory of economic development which leads him to attribute Mexico's past successes too much to fortuitous circumstances and too little to intelligent policies and the inherent, self-sustaining nature of the growth process. On the political side it may well be that Vernon has confused ceremony and function, and that while outwardly the political system may appear to constitute a barrier to further rapid economic development, inwardly the political machinery is capable of producing as decisive and hard-headed economic policies as that of almost any country (and especially, as my Mexican friends have pointed out, as that of the United States). Furthermore, in calling for reform of Mexican political institutions, Vernon perhaps underestimates the advantages of the existing system, given the present stage of the country's social and political, as well as economic, development.

The merits of the political system which has evolved since the Revolution are that it is responsive to public opinion, does permit peaceful changes

of administrations, and at the same time affords wide scope for personal freedom. Centralized decision-making authority vested in a presidency which strives for a high degree of unanimity may seem a peculiar arrangement, but while it imposes certain limitations and involves certain risks it also opens certain opportunities and holds certain other risks to a minimum. It seems clear from a comparison with the record of most other Latin American countries that Mexico's remarkable economic progress in the recent past is attributable in no small measure to the political stability that has been achieved. Furthermore, given reasonably good leadership from the next president and finance minister, Mexico seems more likely to successfully avoid economic stagnation than would be the case if political reforms were to be instituted which, in an effort to establish representative democracy, increased the country's vulnerability to paralysis by powerful legislative bodies or which, in an effort to free the presidency from concern for wide popular support, increased the vulnerability of the government to overthrow by dissident groups.

Whatever the merits of these criticisms, it is clear that Vernon's book will serve a highly useful function in Mexico and elsewhere by stimulating thinking and discussion about these matters. While many of Vernon's critical observations are similar to those occasionally voiced by responsible Mexican intellectuals, it is curious that these same intellectuals seldom are moved to express frankly their concern over problems confronting the country in a form accessible to a wide audience. The fact that this book had to be written by an outsider and the fact that many Mexicans are offended by his unaccustomed frankness reveal an unfortunate deficiency of healthy, objective self-analysis and self-criticism on the part of the Mexicans themselves.

*Rice University*

*Journeys Toward Progress—Studies of Economic Policy-Making in Latin America.* By ALBERT O. HIRSCHMAN. New York: Twentieth-Century Fund, 1963. Pp. xi, 308. \$4.00.

This book is an attempt to push back the frontiers of the subject of development economics so as to incorporate the process of public decision-making in its territory. So far as economic decisions at least are concerned, this is almost virgin land, and the author starts with detailed studies of how three Latin American countries have coped with certain major economic problems—Brazil with its poverty-stricken Northeast, Colombia with its inequitable and inefficient systems of land tenure, Chile with its famous inflation.

The country studies are evidence that, whatever Anglo-Saxons may think, progress really does occur in Latin America, though its path is devious (symbolized, rather enterprisingly, by a reproduction of Paul Klee's "Highways and Byways" as a frontispiece). Setbacks are common; decades pass without any apparent improvement; action when it comes may be a by-product of attempts to solve another problem altogether; it may be the unintended

result of struggle between a number of factions, each of which favors a quite different solution from what finally materializes.

Yet, despite all the apparent chaos in policy formation, patterns are found. In the concluding chapters, the author reaches some descriptive generalizations on the mechanisms of change and uses them to draw normative conclusions on how reform can be achieved without revolution. His conviction that this is usually feasible, even in Latin America, was clearly one force which drove him to pick up his pen; another must have been a compulsion to show the complexity of policy formation. The treatment here of progress as the outcome of the pushing and shoving by many different interests, rather than the creation of a wise policy-maker, reflects his earlier work, which stressed that economic development is generally induced rather than intended. Dislike for sweeping and simultaneous political changes is the counterpart of his professional suspicions of "balanced growth."

The first question that may occur to the reader is: can one detach a really big problem from its national context for individual examination? Each of the three problems he studies is actually part of a total set of interrelated problems, constituting the historic challenge to the country concerned. *All three* countries in fact suffer, though in different degrees, from regional disparities in development, from inappropriate systems of land tenure and from price inflation—as well as from weak commodity markets, inefficient secondary industries, incomplete educational systems, inadequate transport networks, shortages of electric power, etc., etc. It could be argued that the necessarily limited resources of time and money were best spent by the author in studying selected issues of a manageable size; but, considering that a well-known economist is writing, the lack of general economic analyses for each of three countries is rather conspicuous. Even quite limited research would have provided useful background to the story of how each government attempted to deal with the problem chosen for detailed study. It is one thing to say that economic theory needs to take account of political factors, another to leave economics very largely out of the picture.

The paucity of economic analysis is a serious gap in the account of the Chilean inflation, since inflation is after all a phenomenon with many facets. The author of course recognizes this and shows how the theory of "structuralism" emerged as an attempt at a general analysis going beyond a purely monetary explanation, but he does not himself weight the causative influences or trace their interaction. Similarly a study of the problems of the Brazilian Northeast really requires examination of how the system of multiple exchange rates (together with high tariff walls) turned the terms of trade against this region, causing it to fall farther behind São Paulo and the other industrial centers. This criticism can less easily be made of the chapter on Colombia, which does bring out, for example, the role of the foreign exchange shortage in the demand for higher agricultural output; the explanation may be that this is the country with which Hirschman is most familiar.

To raise a more fundamental doubt on his final conclusions, one wonders whether it is not too late by now in Latin America to rely on a consciously

pragmatic, ameliorative approach. Even though it may somehow have worked in the past, this "style" of solving problems is admittedly (perhaps deliberately, if one probes deep enough) slow in producing results. In many countries it may no longer be a realistic description of what actually happens. Military regimes often take action which brings about social reform, but it is the result of running before political hurricanes rather than of tacking to take advantage of every light breeze. As the traditional mechanisms of change atrophy, the patterns of adjustment of policy to relieve growing social pressures seem to be dissolving into a series of sharp and largely unpredictable changes in course.

Even if the past is an adequate guide to the future, the treatment here of the theory of policy-making, complete with algebra and schematic diagrams, seems needlessly ponderous, though fashionable. A Galbraith would doubtless have handled the same material quite differently, and one would hesitate to say that his approach is less appropriate for this field.

Yet Hirschman's central themes are really established beyond question. The ways in which economic policy is formed and institutions adapted are shown to be much messier than is normally believed, or at any rate acknowledged, by economists. Since these changes are part of economic progress, *and yet are not fully determined by it*, the process of development is by implication far too complicated to be fitted into the elegant (or should one say naïve?) fantasies of the model builders.

The country studies also provide additional reason, though from a rather novel point of view, for thinking that economic advisers would be well advised to be either extremely modest or highly sophisticated in their proposals. What Hirschman brings out clearly is that the adaptation of policy to economic requirements consists, if it is made at all, essentially in a process by which those who make or influence policy learn, often unconsciously, from mistakes; political developments impose in time a solution on problems which are not being solved. How many economists realize that the creation and guidance of pressures in favor of a policy are as important as deciding what policy ought to be? Someone in power may even have to adopt a policy which he knows to be wrong, in order to summon up sufficient political support for what ought to be done.

So this is definitely a work to be recommended to economists engaged on development problems. It contains more practical experience than anyone would gain in a decade of work in Latin America and is full of suggestive insights. I was about to add that it is also a useful manual for the reformer—a "progressive" counterpart to Machiavelli's *The Prince*. The reader has the experience (a mildly intoxicating one for the academic!) of being initiated into a number of hard-headed propositions, such as that obscurantism helps to hold together a coalition or that one may have to betray quite consciously one set of colleagues after another (a procedure rather euphemistically described as "shifting alliances").

But here I have my doubts. Perhaps Hirschman's picture of the way society changes is also simplistic; one of the motive forces of progress is pre-

cisely a belief that change will result predictably from a certain political program, and that this will be an easier and quicker process than is in fact at all likely. Both the public and political leaders need a somewhat naïve view of the world if significant advance is to be achieved (just as Columbus had to believe that Asia lay out in the Atlantic if he was to "discover" America). To take away people's illusions may make it quite impossible not merely for these illusions to become reality, but for conditions to be even slightly improved. However, we need not worry lest this book should weaken the forces of change in Latin America. Policy-makers are, from the nature of their calling, too busy to read works on the theory of policy.

*Economic Development and the Use of Energy Resources in Communist China.* By YUAN-LI WU WITH H. C. LING. New York and London: Frederick A. Praeger for Hoover Institute on War, Revolution and Peace, 1963. Pp. xv, 275. \$7.50.

To the increasing flow of literature on Communist China's economy Professor Wu has added this book. However, Wu's study differs from most previous works in that, instead of discussing the general economic situation in that regime or attempting to measure certain aggregate economic indicators such as national income, consumption, and investment, the author investigates one of the vitally important sectors. In fact, this study is probably the most comprehensive survey of the energy industries, chiefly coal and power production, in Communist China in terms of their growth, present situation, and prospects.

This book begins by describing briefly the importance of energy industries for developing countries in general and for Communist China in particular. In the next four chapters the author has assembled, examined, and evaluated the available empirical data concerning production capacity, output, and consumption of power and coal and other related statistics. Although the titles of these chapters refer to the period 1949-60, Wu often extends his data collection back to the 1930's to provide some background information.

Chapter 6 is devoted primarily to the calculation of value-added in the coal and power industries, that is, national income originating from the two industries. In Chapter 7, the author has appraised the successes and failures of the Communist authorities in China in using energy resources and the possible direction of future development.

Just before he summarizes the principal findings and makes some conclusions in Chapter 9, Wu has added a cursory chapter on the petroleum industry, with only 4 ½ pages of textual discussion. One cannot help but feel that the scope of this study would be much closer to the book title if a fuller treatment were given to the petroleum industry. As the author has indicated in Table 59, domestically produced and imported petroleum products com-

bined provided more energy than the power industry in that economy in the late 1950's. The petroleum industry deserves greater attention, especially in view of the possible cut-off of supply of petroleum products from Russia as a result of the Sino-Soviet rift and the drastically increased demand for diesel oil and lubricants in recent years due to the new emphasis on mechanized farming and the greatly increased number of tractors in use.

The reader will easily recognize that discussions of interfuel competition because of changes in the price structure in the fuel market, government regulations and other policy implications, which usually occupy a preponderant space in most research reports on fuel industries in the Western countries, are conspicuously missing in Wu's book. It is largely because of the institutional differences between the two types of economies involved. Wu's book, like most other works on Communist China's economy, is primarily informative in nature.

A great amount of statistical data has been compiled in this study. Part of them are official data gleaned from various Chinese Communist publications while the rest are estimates derived by the author himself on the basis of other relevant information. However, on some occasions it is not clear whether the author has made his own estimates simply because no official data are available or because the official data, though known, are regarded as unacceptable. For instance, in calculating the sectoral breakdown of power consumption in various years, Wu has accepted (p. 78) the industrial power consumption figures for 1952-56 given in *Major Aspects* but has not made use of similar figures given by the same source for 1949-51. Instead, he has taken a very roundabout process (p. 81) to arrive at some estimated figures for 1949-51, which differ insignificantly from the official data.

This leads directly to a broader issue, that is, whether or not the estimated figures in this book are reasonable approximations to the facts. There are a few sets of estimates whose validity is extremely questionable. Table 21, entitled "Electricity Import and Export," is an example. For 1952-56, the difference between the estimated "net domestic supply" and the estimated "total consumption" of electricity has been "attributed" to import or export (p. 81), depending on whether the difference has a minus or plus sign. For 1951 and 1957-60, it is uniformly assumed that Communist China had imported annually 152 million kwh of electricity from North Korea (p. 79). It seems to me that the so-called import and export of electricity in 1952-56 are nothing but statistical discrepancies between the estimated net supply and the estimated consumption. In the first place, Wu has not cited any documented evidence, official or otherwise, to prove that export or import of power has taken place in Communist China since 1951. Secondly, it seems peculiar that Communist China alternated from year to year between exportation and importation in a varying quantity. Ordinarily, power exchange between two countries, with or without a long-term agreement, would have, at least in a short period of time, a fairly stable pattern in which one country is the net exporting party and the other net importing party every year. Thirdly, it is even more doubtful that North Korea would be able to export 152

and 141 million kwh of electricity to Communist China in 1951 and 1952, respectively, when she was suffering from the most serious power shortage in her history owing to the Korean War. According to North Korea's official data, even in 1953 when large-scale military activities had already been discontinued and the truce was signed in July, her electricity output was restored to only 16 per cent of its 1949 level.<sup>1</sup>

To avoid further confusions about the already complicated names of places transliterated from the Chinese, it would be desirable to unify the transliterations if the city is the same. For example, Nan-ch'ung (p. 209), a city in Szechwan, becomes Nan-tung (p. 208); Chang-tu (p. 207) in the former Hsikang province is changed into Chamdo (p. 205); both Chang ch'ang (p. 208) and Chang-Chong (p. 209) are used for the same city in Hainan.

Reference is repeatedly made (p. 82 and p. 248) to "Appendix C"; there is no such appendix in the book.

Nevertheless, all the stains mentioned above do not invalidate any of the major findings and conclusions in this book. Nor are they damaging to its valuable contribution to our knowledge and understanding of the energy industries in Communist China. The book can be recommended either as a source of reference for China specialists or as a comprehensive study in this field to nonspecialists.

Finally, we share the author's hope that the "sectoral approach" or "analysis in depth" exemplified in this book "could mark the beginning of a new stage in the development of the Western World's information on Communist China."

<sup>1</sup> See *Joint Publication and Research Service*, 901, January 15, 1960, p. 182. Other sources have indicated that Communist China was responsible for the reconstruction work of the Suifung hydro-electric plant on the Yalu River, which was completed only in 1958, and that the part of the restored generating equipment supplying electricity to Manchuria has been included in the official figures of total generating capacity in Communist China. See *Far Eastern Econ. Rev.*, April 8, 1954, p. 437 and *Chugoku Kenkyu Geppo*, Tokyo, No. 131, Feb., 1959, p. 15.

*The Development of the Indian Economy.* By W. B. REDDAWAY. Homewood, Ill.: Irwin, 1962. Pp. 216. Paper, \$3.75.

This is the first volume in a series of studies on the Economic Development of India conducted by the Center for International Studies at M.I.T. The book is supposed to give an over-all view of the development of the Indian economy and it does this job remarkably well. However, for those interested in a critical evaluation of Indian planning, the book does not promise too much. Most of Professor Reddaway's writing seems to be colored by the opinions of the people in the Planning Commission and in the Indian Government Service with whom he had close contact.

Part I of the book is titled "Analysis of the Problems." In this section Reddaway first discusses the limits to the growth of India's national income.

Chapter 1 mentions the population problem as the major limiting force. Chapter 2 discusses the nature of the unemployment problem in India. Chapter 3 on "International Considerations" mentions the limits to the expansion of export earnings, and Chapter 4 discusses the limits to the expansion of individual sectors. The next three chapters are devoted to planning techniques. Chapter 5 is on the "Broad Strategy of Development." Chapter 6 on "Some Problems of Choice" is a chapter on choice of technology and has a discussion of labor-intensive techniques. It is really surprising that this is the only problem of choice that has received the attention of Reddaway. Chapter 7 on "Planning in Practice" gives the basic principles of planning techniques. The major drawbacks of this section are the complete neglect of problems of monetary-fiscal policy and the prosaic discussion of international trade policy. Reddaway merely repeats the general view current in India that it would be extremely difficult to secure a substantial net increase in India's exports. As is common with this argument, he starts with tea, jute, etc. There is no discussion of the problem of devaluation or the drawbacks of India's foreign trade policy (the licensing scheme and thousands of rules, regulations, exceptions, taxes and subsidies). One relieving feature of this part of Reddaway's book is his discussion on labor-intensive techniques (pp. 72-77), wherein he corrects the mistakes in the logic of some proponents of these techniques. The problem of "choice of techniques" has a very strong hold on the minds of many Indian economists. Most of the confusion in this field could have been avoided by a precise specification of the objectives.

Part II presents a model of the Third Plan Period. This model closely approximates the official Third Five-Year Plan both in the assumptions and in the basic data. However, the carefulness with which Reddaway has handled the data and the systematic conceptual framework he has set up would be very useful for those working with problems of development planning. This section is very tedious and many of the things said sound obvious. However, Reddaway has done a good job in working out this exercise in detail and many of the people working in the Planning Commission will benefit from it. This is corroborated by the footnote on page 169 wherein Reddaway gives the opinions on his article on "Importance of Time-Lags for Economic Planning" (which is reproduced as Appendix A of the book). An English noneconomist's comment was "Well, that is all very clear and easy to understand, but it seems so obvious that I do not see why you need to write it"; an official concerned with Indian planning, on the other hand, said that he found the analysis most useful!

The appendices contain the reproduction of a couple of Reddaway's articles published in the Indian economic journals. One of these is the article on the capital-output ratio. No other concept seems to have such a strong hold on the minds of the Indian planners as this ratio. It is high time the limitations of this concept are emphasized. Unfortunately, Reddaway does this job only cursorily. The capital-output ratio is essentially a useless concept for problems of resource allocation or estimation of investment require-

ments. It has been long established in economics that these problems cannot be tackled by the use of capital-output ratios. Even the limited use of the capital-output ratio in industry in the underdeveloped countries rests on the by now well-discredited theory of zero marginal productivity of labor in agriculture in these countries. Looked at from every possible angle the concept is essentially useless (and its use dangerous) for planning resource allocation and estimating investment requirements. The use of marginal and sectoral capital-output ratios does not change the nature of the problem.

On the whole, Reddaway's book is very interesting and will be useful to many interested in Indian planning. However, the book would have been more useful if the theoretical issues had been discussed more elaborately.

*Stanford University*

*The Political Economy of Mexico—Two Studies.* By WILLIAM P. GLADE, JR. AND CHARLES W. ANDERSON. Madison: University of Wisconsin Press, 1963. Pp. vii, 242. \$5.00.

This book is comprised of two separate monographs growing out of the authors' participation in the Ibero-American Studies Program at the University of Wisconsin. The one written by Professor Glade is entitled "Revolution and Economic Development: A Mexican Reprise," and the one written by Professor Anderson is entitled "Bankers as Revolutionaries: Politics and Development Banking in Mexico." The justification offered for combining these two rather disparate studies under a single cover is that they "share as a common theme the saga of Revolutionary Mexico and its economic progress" and constitute "experiments in the use of interdisciplinary approaches as a way of getting at some of the basic problems of economic development" (p. v).

The basic hypothesis of Glade's study is that there is an "essential unity" to be found in the totality of Mexico's post-revolutionary economic and social experience, and that it is to the Revolution and the many changes it produced that one must look for the explanation of Mexican economic development. Accordingly, his study represents "an attempt to trace and appraise the impact of the several components of the Revolution on two sets of variables, sociological and economic, which bear on the capacity of the Mexican economy to produce ever larger outputs over time" (p. 23). This difficult assignment is complicated by his decision to employ "a 'field' concept of interacting forces rather than the more mechanistic concept of cause-and-effect relationships" (p. 23) as the basis of analysis. Thus he is led to search for evidence in a wide assortment of sociological, economic, political, anthropological, psychological, and artistic literature, relating to the experience of modern Mexico. Indeed, one of the most impressive things about Glade's work is the manner in which he has been able to draw upon the findings of many specialized observers in support of his thesis. But while he is deserving of congratulations for a good effort in attempting to carry out a difficult assignment, perhaps it is neither uncharitable nor evidence of lack

of sympathy with the interdisciplinary approach to suggest that Glade fails to develop a really convincing interpretation of either the Mexican Revolution or the record of post-revolutionary Mexican economic development—and certainly not of the relationships between the two.

In the same way that Glade's study is intended to have general relevance to "the problem of revolution as a possible precondition for economic growth" (p. vi), Anderson's piece on Mexican development banks is offered "as a case study whose relevance extends beyond the particular example under consideration insofar as it serves to explain the political process that surrounds all institutions of this type" (p. 108). More particularly, however, Anderson is concerned to show how the Mexican banking system has been employed as a means for both stimulating and regulating the process of economic development in accordance with prevailing political realities.

Anderson's monograph is marred not only by superficiality but also by occasional lapses into uncommonly opaque and evasive language. Furthermore it contains numerous erroneous statements (e.g., monetary policies during the 1930's were not conservative as claimed on page 120 nor were the first attempts to centralize the issuance of paper money made in the 1890's as implied on page 118) and questionable judgments (e.g., in the opinion of this reviewer Mexico has not modelled its development banking system excessively on those of other countries as suggested on page 184, but rather has, on the one hand, been quite original in devising institutions and procedures appropriate to its own peculiar circumstances and, on the other hand, has so far failed to borrow from abroad certain financial techniques which could be quite helpful). However, Anderson's basic contention that understanding of the Mexican system of development banks requires an appreciation of the political forces giving rise to the system and conditioning its operation is quite correct.

*Rice University*

*The British Economy in the Nineteen-Fifties.* Edited by G. D. N. WORSWICK AND P. H. ADY. New York: Oxford University Press; Oxford: Clarendon Press, 1962. Pp. xi, 564. \$8.00.

This is a first-rate (and sometimes quite lively) analytical and critical survey of economic events, developments, and policies in Britain during the decade of the 'fifties. Like its predecessor, *The British Economy, 1945-1950*, it consists of a series of carefully interlaced essays and papers by a group of Oxford economists under the editorship of G. D. N. Worswick and P. H. Ady. The high standard set by the previous book is maintained, if indeed it is not exceeded, by the present volume.

The book as a whole is for the informed general reader, yet its array of special chapters furnishes solid fare, as well, for the specialist scholar. A tightly and most competently written introductory chapter by Worswick presents an over-all running account of the period. It is followed by parts on "International Trade and Payments," on "Government and the Economy," and on

"The Consumer, Capital and Labour Markets." There is an annotated bibliography. The book gains much in interest and usefulness from its varied authorship; and, because of the skill with which the separate chapters have been planned, prepared, and put together, the gain has been purchased at a very low cost in direction and unity. There is something here for every economist—macro, micro, industrial, agricultural, labor, international, monetary, fiscal, consumer, everyone.

Turning to the chapters in which this reviewer finds himself most at home, those devoted specifically to Government and the Economy, the book treats of general regulations and controls affecting all or a large number of industries, of specific interventions in the affairs of particular firms or industries, and of more permanent or continuing policies toward particular industries. In all of these categories, typical cases are examined, and a critical analysis is made of programs and policies. In most instances the Government comes out considerably bruised and shaken from the examination—but it does come out, and under its own power! Not in all cases, but in most, the attack is delivered more against *the* program than against *a* program.

The relaxation of direct wartime controls was well advanced by 1950, but the trend was interrupted by the Korean affair. By the end of 1954, however, "the structure of controls had been largely dismantled," but still with some varied and interesting "survivals." A person unfamiliar with what had gone before could be pardoned for failing to appreciate that the galaxy of controls that still remain in Britain constitutes only a dismantled structure. With reference to the extent and pattern of the program of elimination, the book points out that it is probable that "the change of government in 1951, and the success of the Conservative Party in the two subsequent elections, made less difference than is often supposed" (p. 334). All of this, together with the fact that in several important instances (e.g., price controls over iron and steel scrap) business itself did not favor abolition of controls, suggests that a *British Economy in the Nineteen-Sixties* will almost certainly be compelled to devote even more space than does the present volume to the section on Government and the Economy.

In dealing with "Specific Interventions," and after making clear that the treatment does not pretend to be exhaustive, the book does a real job on government actions taken on sulphuric acid, titanium, fuel oil, locomotives, the "siting" of steel strip mills, the "rescue" of the cotton textile industry, and Cunard and the two "Queens." The treatment, under a full head of steam, continues with reference to the "Continuing" policies of government in relation to private industry; it loses none of its force as it rides over government and steel and government and the aircraft industry. Scarcely pausing to change authors, the drive proceeds relentlessly in the chapter "The Nationalized Industries" to take apart government investment and pricing and coordination policies in the fuel and transportation industries.

— Students of British regulation and public enterprise have become familiar with the propensity of British government agencies to worry about, and ever-

lastingly to experiment with, procedures and forms of organization. Awareness of the importance of procedures and organization in controlling and operating economic ventures in the context of British democracy, and frequent revision and reorganization in the wake of a steady flow of studies and enquiries, are imbedded in British thinking and practice. One gathers from the present study that even more introspection and retooling are in order. Four features of the British machinery of government are named which "make it difficult for questions of economic policy to be properly considered, and which collectively have an obvious effect on the quality of decisions taken by British governments": (1) the marked tendency to look at problems in strictly departmental terms (the danger is accentuated by the dual role often played by the Treasury—formulating general economic policy, and laying down economic criteria for policy decisions on the one hand and controlling and minimizing government expenditure on the other); (2) almost exclusive concentration on problems of immediate importance; (3) "a strong preference for secrecy and informality, for withholding information and preventing or abbreviating public discussion" (a practice rarely questioned even by the party in opposition); and (4) the failure to ensure that specialized economic advice is available within the departments which are necessarily concerned with economic questions (pp. 374-77). The tendency of Ministers to intervene in details of the management of nationalized industries without taking responsibility for failure of policy and the failure of the Government until after the close of the decade to announce a policy on the application of the nationalization statutes are thrown into the indictment for good measure. It is added that the policy as finally announced "codifies the muddles of Whitehall thinking and evades decisive judgments in the fields where it might be thought the business of Government to decide" (p. 416).

Worswick, in his introductory chapter, also pays his respects to the Government's general economic policy. Until the middle of the decade, the Government "appears not to have had any very definite economic aims"; thereafter, the Government seems to have regarded interrelated objectives of policy as "separate problems, which might be solved piecemeal and *seriatim*" (p. 72). The changeover from the use of direct control to "global" regulators comes in for questioning: to work, indirect controls must have the impact on individuals of direct controls, but they are less effective. Their use coincided with the "Government's preference for backstairs intervention" (p. 72). Finally, in a paragraph developing the theme that "The Government relied far too much upon an implied harmony of private and public economic interest," Worswick really punctures the "admonition to be responsible" balloon—a feat in itself worth the price of admission. Indeed, at this point the American reader is likely to turn to the title page, to make certain he is reading about the United Kingdom rather than the United States. It occurs to me that the same reader, if he is a professional economist, might pause for a moment as he races through this and other formidable accounts of governmental shortcomings, to consider whether, as economists, we might help mightily in

the business of government regulation and enterprise if we were to forego some of our insistence upon unattainable precision in these matters and were instead to attempt the formulation of simpler, blunter ends that are worth attaining and are attainable with the kinds of tools available to a democratic society, and which we might help to devise.

There are many places in the book at which discussions of, or comments on, British economic policy problems or practices strike the reader as having special relevance to the American scene. There is an excellent formulation of the "self-finance" problem that arises in determining the pricing and investment policies of regulated and nationalized industries (p. 425), which should be translated and made required reading for our own regulatory commissions. And throughout the treatment of the transportation morass there lurks an understanding of a problem that defies understanding. What are we political economists going to do with this transportation problem, anyway? It is difficult enough for us to proceed rationally where a discernible line can be drawn usefully between industries where competition works and where it doesn't work, and where the industries have some respect for lines. But where, as in transportation, the several component industries insist not only on crossing and recrossing all lines but in intermingling and cohabitating indiscriminately, the problem is clearly beyond us. We must, of course, continue and extend our studies, but only two lines of active policy seem open: to move in with a club, swinging, or just to relax and ride and ship.

The chapter on the consumer sector contains a brief, but informative, run-down on Britain's brave new experiment in antitrust, the 1956 Restrictive Trade Practices Act. In the British approach to the problem of monopoly, it is said, "the complicated valuations involved in the disposal of welfare issues are faced as each issue arises" as distinct from the U.S. approach which simply adopts "the particular set of valuations involved in the concept of the competitive optimum" (pp. 451-52). "The ending of some restrictive agreements was followed by mergers, and perhaps the 1956 Act was a contributory factor," but, at least, "by 1960 there was far more price competition . . . in British wholesale and retail trade than there had been before 1956, and the provisions of the . . . Act prevented this return to price competition from being frustrated" (p. 457). Well, we shall see.

"Measured by almost any of the available indicators, the fifties was a decade of economic progress." Production and consumption rose, consumer durables were extended to mass consumption; employment was full, and the area of economic freedom at home and the ability to spend abroad were expanded (p. 68). However, "the fifties ended on the note of record Christmas sales, but one could just hear voices saying that the sixties might bring the need for a new approach to economic policy" (p. 74). And, possibly, a new Government?

BEN W. LEWIS

*Egypt in Revolution—An Economic Analysis.* By CHARLES ISSAWI. New York: Oxford University Press for Royal Institute of International Affairs, 1963. Pp. xiv, 343. \$7.20.

Robert Solow wrote that: "Productivity may turn out to be the hot subject of the 1960's in economics." This reflects his parochial interests and neglects the issue not only of the 1960's but the one which will predominate throughout the remainder of this century—economic development. Many different theories ranging from the essentially Adam Smith variety to the full-blown modern Marxian type are currently being tested, explicitly or implicitly, in countries from Asia to Latin America. Potentially the analysis of the development process under various theories could be influential in guiding the choice of future strategies. Unfortunately most books about developing countries concentrate on describing change, rather than analyzing it. Typically they open with a few chapters of historical notes to set the scene, followed by a section which describes the objectives and framework within which current development is proceeding, then the bulk of the book is filled in with a sector by sector description of the structure of the economy, and finally a closing chapter summarizes the prospects the country faces. Economics desperately needs a James Joyce or a Lawrence Durrell who can put the interconnecting parts into a huge literary matrix where the interdependence becomes explicit and a new time dimension is added.

Professor Issawi has not attempted to forge a new frontier among contemporary historians. He offers a conventional study of present-day Egypt and how it got that way. The analysis of economic change clearly takes second place to describing the change. This is not to suggest the book is devoid of theory. The topics which have become the principal theoretical issues of economic development are scattered throughout the book, but they do not form the basis of its framework. Rather they provide an occasional interlude between facts, facts, facts.

A small but random sample revealed that there are probably about 22 quantitative data on each page, something in the neighborhood of 7000 quantitative facts in the book. In it we learn *inter alia* that:

... between the Revolution of 23 July 1952 and 1961 the share of national income absorbed by the government rose from a little over 20 per cent to some 60 per cent ...

... in 1961 the President declared that 95 per cent of industry is either owned or controlled by the government ...

... deserts constitute 95 per cent of the country ...

... whereas in the United States in 1945 an average acre of farm land was worth the equivalent of less than 10 days of the average worker's wages, in Egypt an equivalent farm land claimed a price equal to about 20 years of the average worker's wages ...

... all imports are now made through government-owned companies ...

... the government is responsible for 4/5 of total investment ...

... the total output of Egypt is probably not much larger than that of a city like Baltimore with a million inhabitants ...

. . . its population density on the inhabited portion is one of the very highest in the world at over 650 persons per square kilometer. . . .

These and other facts are remarkably useful to describe recent changes and in putting modern Egypt into a proper context, but on sum the sheer volume of them becomes a powerful sedative.

The book is organized into four distinct sections. The first comprises three chapters which set the historical background. In the preface the author has said that "during the last ten years Egypt has undergone more radical changes than at any other time in its long history, *with the possible exception of the 1820's*" (italics added). This earlier period of forced industrialization is, however, inadequately discussed, and no comparisons are made between it and the present development efforts. This section is followed by a lengthy chapter on Arab socialism (in Egypt) between 1952 and 1962, its development and ambitions. Civilian influence predominated between 1952 and 1956, but since then Egypt has become a "totalitarian socialistic state" due largely, in the author's opinion, to events beyond its control: Baghdad Pact, Suez, High Dam affair, and the general "world wide trend towards socialism and planning." Unfortunately neither of the critically important aspects of a centrally planned economy, the planning process and the methods of execution, is adequately discussed. Then comes the bulk of the book in eight chapters, each dealing with a different sector, the usual descriptive topics familiar to readers of development plans: human resources, national income, agriculture, industry, transport and communications, foreign trade and balance of payments, finance, and public finance. The final chapter begins with a long summary of the problems of developing countries generally and concludes with the problems Egypt will face in the future, about which the author is "convinced that Egypt's long-term prospects are good because it should, eventually, be able to make fuller use of its deserts." This is cold comfort indeed considering that no one has yet been able to break through the technological barrier to make the deserts bloom.

The book's accessories include a convenient table of conversion factors for the local Egyptian measurements, a practice which should be followed in all books of this sort. There are three short appendices. One lists public organizations by the controlling ministry. Another discusses various estimates of investment between 1946 and 1961. The last gives a few descriptive paragraphs about "the main facts regarding capital, employment, equipment, and output in the principal industries, as well as plans for expansion." Those wishing to pursue further specific aspects of Egypt's development will regret the absence of an extensive bibliography. The chapters are, however, heavily footnoted and the principal UAR official publications have been listed. French, German, and Latin are required to make sense of the several quotes which preface each chapter. This is certain to irritate those readers who feel that Max Schulman's sublime satire should have put an end to such practice.

Even though many economists would be hesitant to use *revolution* to describe economic change (especially those who have been closely involved

in advising, assisting, and encouraging progress among developing nations), no reader of this book should object to its use. Issawi has masterfully amassed the pertinent data documenting the economic revolution of post-Farouk Egypt and has provided enough extra data to confirm social and political revolutions as well. In closing and without offering a judgment the author poses a perplexing problem for the West: should it continue to support Egyptian development when its avowed aim is to spread Egyptian influence and its brand of Arab socialism throughout the Middle East and Africa?

Originally an active participant in Egyptian economic affairs, Issawi writes in this third and final study from an objective and detached position. Because of the facts and source references it contains, this book will become a standard text on contemporary Egyptian development. But owing to its emphasis on description, it cannot be generally recommended for its analysis of development under centralized planning.

### **Economic Systems; Planning and Reform; Cooperation**

*Problemy optimal'nogo planirovaniia, proektirovaniia i upravleniia proizvodstvom.* (Problems of Optimal Planning, Project-Making and Production Management.) Moscow: Moscow University Press, 1963. Pp. 546.

In the two years that elapsed between the path-breaking conference on mathematical economics of April, 1960 and the "Theoretical Conference" held at Moscow University in March, 1962, the proceedings of which form the subject of this review, by far the most significant development was the revival of Soviet interest in demand theory. When we recall the pioneering contributions of Russian economists in this field in the first quarter of this century (by Eugene Slutsky, A. A. Konüs *et al.*), the intellectual poverty of the last three decades seems bleak indeed. Not only was utility theory ruled out in Stalin's time—as subjective, idealistic, and generally un-Marxist—but even the notions of income and price elasticity were discarded. A few years after the death of the Soviet dictator, these fundamental concepts crept back into statistical work and even acquired a modest measure of ideological respectability; yet the more abstract aspects of "bourgeois" demand theory were still resolutely condemned. When, for instance, Konüs, interrupting a long period of silence, exceptionally introduced a utility function in a theoretical paper he wrote for the *Festschrift* in honor of Academician Strumilin in 1957, he was soon after taken to task for doing so by A. Boyarsky, who for several years appears to have acted as the chief custodian of ideological purity in matters of mathematical economics. By 1962, however, the liberal school of Soviet mathematical economists had become strong enough to convoke and to dominate a conference under the auspices of the Department of Political Economy of Moscow University, known hitherto as a bastion of orthodoxy. The first group of papers presented at the Conference all dwelled at some length on the problem of formulating objective functions for programming purposes and of determining the relation between these functions and con-

sumers' preferences. In my comments, I shall deal only with the Conference papers of wider economic significance contained in this first group, while generally recommending to specialists in operations research the wide selection of papers on the optimal location of production activities, transportation problems, investment efficiency, and production scheduling contained in the rest of the volume.

The first paper presented at the March 1962 Conference, by V. A. Zhamin, a political economist at the University of Moscow, sounded the keynote of the proceedings:

It is well known that in the period of the cult of personality attempts to apply mathematical methods to economics received no support whatever. Relapses of this incorrect attitude to mathematics have been preserved in the consciousness of many economists to the present time. This serves as a direct hindrance to the progress of our economic science. The nihilistic attitude to mathematics is reflected, in particular, in that the works of bourgeois economists of mathematical orientation are often subjected to criticism, not for real mistakes and for the conclusions drawn from them, but for using the mathematical apparatus, for the use of terms, if the latter did not yet appear in the classical works of Marxism-Leninism or appeared in these works in some other aspects.

As a result, a few questions of importance for theory and practice are not worked out, because the specialists are aware that a serious investigation would necessitate the use of these terms. Why, for instance, are there practically no theoretical studies on the analysis of consumer demand in our literature? Ask the comrades dealing with these problems. They will answer: because the serious analysis of these problems requires the use of such concepts as utility, consumer preference, etc. And for these concepts one may be criticized (pp. 9-10).

A. Boyarsky, whose paper followed Zhamin's, fought a rearguard action in favor of a theoretically conservative approach to the use of mathematics in economics. Compared to his speeches at the Conference of April, 1960, he was willing to make limited concessions on marginalism and on the use of objective functions to solve economy-wide problems (as long as there were several such functions and a number of variants of the over-all plan which the authorities could choose from), but he was adamant in his rejection of shadow prices for economy-wide problems and in his refusal to recognize the notion of opportunity cost. Instead of letting sleeping dogs lie, Boyarsky, by stressing the doctrinal deviations of his opponents who dominated the Conference and by the weak arguments he summoned to defend the orthodox position, opened himself to rebuttals that probably did more harm than good to his cause. His more dogmatic theses were easily demolished in the discussion that followed the papers by a phalanx of critics including Konüs, V. A. Volkonsky, I. Girsanov and A. Lurie. The last two pointed out that Boyarsky was virtually the only participant at the conference to hold his obsolete views.

L. M. Dudkin of Moscow University, in an interesting paper on a "Mathematical-economic Scheme for an Optimal Material Balance of the Socialist

National Economy," made some specific suggestions as to how demand theory ought to fit into the task of designing planning models. The objective function—the maximand—of such models, he argued, should be "the greatest possible satisfaction of working peoples' needs," which, it is clear from the context, he interpreted as a Pareto optimum for consumer goods (p. 42). Dudkin recognized that the planners would have to ascertain the preference orderings of consumers "to enable us to choose the most preferred point consciously." Was there anything ideologically objectionable in that? Not at all, he alleged, since the existence of preference functions is implied by the existence of consumers' demand functions for every given set of prices and incomes. To substantiate this mathematical relation, he calmly referred his Soviet readers to the proof by H. Uzawa of Stanford University. He then went on to prick the dogmatists for the inconsistency of their position:

The working peoples' function of consumer preferences is nothing else but the counterpart of their demand function, and is really only its other mathematical expression, the result of the mathematical transformation of a demand function. This transformation is no less justified than any other mathematical transformation used in the concrete sciences. This will be confirmed by any mathematician who understands the real nature of the problem. Consequently, those who speak out against the use of the apparatus of consumer preferences without objecting to the use of demand functions are in fact opposing the legitimacy of applying mathematics to economic research, and withal, to economics (p. 43).

Although Dudkin recognized that consumer preferences should be corrected in the light of scientific research in the interest of society as a whole, he thought it was best to start off from these preferences and only then to make specific corrections for individual products, "inasmuch as there is not a single planning and scientific organ at the present time that is in a position to evaluate better than the consumers themselves the relation among their complex and variegated material and cultural needs (which relations evolved objectively in the course of long experience)" (p. 45). Volkonsky, in his oral intervention, added to Dudkin's arguments that catering to consumers' preferences was the "democratic approach" to the planning problem. These defenses of the rationality of consumers' choice strike a new note in Soviet economic writings, as does the postulate of consumers' sovereignty underlying Dudkin's entire model.

Dudkin sketches out his scheme in its static and dynamic aspects, maintaining in both cases his assumption of linearity in the constraints, but he fails to elaborate the mathematical properties of his models. These more technical aspects of the Dudkin model are taken up by the mathematician I. Girsanov, who, in an independent paper, examines the minimum assumptions required to build an operational program geared to consumers' preferences expressed in a free market for consumer goods. He finds it necessary to postulate diminishing marginal utility for every good and to make all goods gross substitutes. In the model he elaborates, the prices of consumer goods are those that would obtain if the quantities determined in the program were sold on

a free market. For calculation purposes, capital goods and intermediate goods would be assigned the implicit prices of the constraints imposed by the availabilities of these factors during the planning period. The entire labor force, he assumes, would have to be employed in every admissible program. Wages for different categories of workers would be endogenously determined in this centralized model (via prices and productivities). The planners' problem, in short, would be to find a bill of consumer goods that would generate an acceptable wage distribution corresponding to the prices for all goods in the system.

Finding an optimal solution to the Dudkin-Girsanov model would be tantamount to simulating a general equilibrium in a market economy. Was Enrico Barone excessively pessimistic when he warned at the turn of the century of "the difficulties—or more frankly, the impossibility—of solving such equations a priori"? Girsanov claims that an algorithm *can* be devised to solve concrete programs, within the limits of the linearity and other simplifying assumptions he builds into his model. It will be instructive to watch what further progress he and his colleagues will make in this direction.

Although Girsanov confines his speculations to the static model, he suggests that he could extend his results to a multiperiod scheme. To do this, presumably, the planners would have to know, in addition to the demand functions of consumers for all goods and prices in each period, their preferences for incomes accruing in different periods (if not their intertemporal preferences for every good). Dudkin and Girsanov seem to be so neoclassical in their conceptions that one may wonder whether they would accept Pigovian restrictions on consumers' sovereignty; whether, for example, they would allow that the economy's aggregate rate of saving determined by the intertemporal preferences of consumers must be corrected for their myopic appreciation of the future benefits of present sacrifices. (After years of austerity imposed on consumers by presbyopic planners, there is perhaps something to be said for letting consumers have things their way.)

What is the potential significance for planning practice of these models? Are these the Soviet equivalent of the Utopian visions and pipe-dreams of nineteenth-century economists? Or is there a real chance that they will be seized on to aid the planners in drawing up their plans? At this juncture, I cannot envision the Soviet authorities ministering to the sovereign interests of consumers. If the mathematical economists wish to do more than "play with numbers," as Stalin once taunted them, they will have to incorporate into their models the objectives laid down by the Communist Party, which are likely to diverge seriously from those that could be read from the revealed preferences of consumers. The question is, then, whether the Party authorities will be agreeable to making these objectives explicit enough to enable their translation into mathematical language. Will they be willing to put numbers on the relative priority of armaments and consumer goods? "Scientific planning" may entail the abandonment of certain time-consecrated practices, such as the setting of unattainable goals for farm output and for standard-of-living increases, which serve a hortatory purpose in mobilizing the pop-

ulation for support of long-range plans but which are undermined, in the course of executing these plans, by *ad hoc* allocation decisions deflecting resources from low-priority uses.

Girsanov, incidentally, hints that it may not be easy to find a common language with the operational planners, but he begs the question when he suggests that "one should separate theoretical from practical questions, and abstain from dealing theoretically with a number of difficulties that may be solved in practice by the intuition of the planners" (p. 68). For who is to draw the line between hidebound routine and intuition, between poor judgment and the fruit of long experience?

Once the semantic problems have been solved, the theoreticians will at last be in a position to confront their ideas and thrash out their differences with the administrators of the Soviet economy. If the highest authorities decide to let the views of the mathematical economists prevail, then a re-examination of the goals of Soviet planning may be in order. But if these economists are forced to back down, they may well have to confine their efforts in the future to areas that are less sensitive politically than the design of objective functions for nationwide planning.

### Business Fluctuations

*The Puerto Rican Economy and United States Economic Fluctuations.* By WERNER BAER, Rio Piedras, Puerto Rico: Social Science Research Center, University of Puerto Rico, 1962. Pp. xvi, 155.

The stated purpose of this study is "to analyze the past, present, and possible future effects of economic fluctuations in the United States on the Puerto Rican economy" (p. 1). Actually, the study is much less ambitious, for it deals mostly, though intensively, with the effects on Puerto Rico of only the downturns of U.S. economic activity in only two instances, 1953-54 and 1957-58. The conclusion is that "the two Mainland recessions in the 1950's revealed a very mild reaction on the island. The 1953-54 recession was mainly felt through a substantial decline in net migration, thus causing a rise in unemployment. In the 1957-58 period the recession was passed on mainly through a widespread production curtailment of older firms in the export industries" (p. 141).

Despite the objective evidence provided by his statistical analysis, the author contends that "the true sensitivity of Puerto Rico to the Mainland cycle" (p. 141) was not manifested by Puerto Rico's reactions to the two downturns of the 1950's, principally because of the rapid growth of the island economy—a 70 per cent increase in real gross product from 1947 to 1958 (p. 16). He spends most of his pages uncovering institutional and structural changes which bear on the "real" sensitivity of the Puerto Rican economy.

One institutional change is the tendency toward lower excess reserves held by Puerto Rican banks. These reserves have in the past cushioned the economy from the impact of Mainland credit restrictions. A structural change of note is the increasing relative dependence of the Puerto Rican economy on exports: exports of goods and services as a percentage of gross product rose from 32 per cent in 1939-40 to 44 per cent in 1947-48 to 53 per cent in 1956-57. Over 90 per cent of both exports and imports have been with the U.S. Mainland all along (p. 18). Closely associated is the change in the type of exports. Food, for example, accounted for 70 per cent of exports in 1947-48, but for less than 30 per cent in 1957-58. A rather ingenious approximation of income-elasticity analysis, for U.S. commodity groups that include most Puerto Rican exports, "revealed that Puerto Rican exports are increasingly concentrated on products experiencing sharper fluctuations over the cycle" (p. 143). Imaginative use of the Leontief input-output table for the U.S. economy in 1947 enables Baer to calculate that the "changed commodity structure of exports . . . reduces the island's sensitivity to the Mainland cycle by increasing the import content of exports from not quite 11% to over 19%" in a decade (p. 122). In another statistical exercise the author relates "fluctuations in exports and labor earnings when both seasonal fluctuations and the trend have been eliminated" (p. 30). From very limited statistical evidence "it was estimated that without the mitigating growth factor, fluctuations in exports would have had an effect on labor earnings three times as powerful as was actually experienced in the last two recessions" (p. 147). A chapter is devoted to a detailed analysis of the behavior of a selected group of firms in an attempt to discover their reactions to Mainland recessions. The conclusion is that in the absence of the growth factor "fluctuations would be passed on in a slightly magnified way" (p. 107).

Baer does not, in the opinion of the reviewer, successfully demonstrate that the Puerto Rican economy will be increasingly vulnerable to U.S. recessions as the island's growth rate tapers off. In fact, on the basis of the reviewer's investigations, export instability for a country tends to be positively correlated with growth and negatively correlated with foreign trade involvement (ratio of trade to GNP).

Baer's study is far from being a model monograph. It bears the earmarks of having been rushed into print. It lacks precision, care, and polish. Boldness rather than scientific caution characterizes the drawing of inferences from the statistics. The author seems to be trying to prove a case instead of testing an hypothesis. The theoretical observations at the start and the policy discussion at the end could have been omitted to advantage.

In spite of these critical comments, the study tells much about the Puerto Rican economy and is an addition to the small stock of empirical studies dealing with the problem of international or interregional propagation of economic instability, a problem that has defied meaningful general theorizing.

*Earlham College*

**Money, Credit, and Banking; Monetary Policy; Consumer Finance; Mortgage Credit**

*The Composition of Consumer Savings Portfolios.* By HENRY J. CLAYCAMP. Urbana: The Bureau of Economic and Business Research, University of Illinois, 1963. Pp. x, 99. \$3.25.

Theoretical and empirical analysis of portfolios is gaining increasing attention from two major groups of economists: those who attempt to explain consumer behavior by explicit reference to motivating conditions and forces and those who are developing saving functions by breaking total saving into changes in individual assets. Claycamp's study is a contribution to the stream formed by, among other studies, some publications by George Katona and the paper by Harold Watts and James Tobin, in *Proceedings of The Conference on Income and Consumption*, Vol. II.

The basic hypothesis of the book is that ownership of any given asset does not affect the probability of ownership of any other asset. This "independence hypothesis" predicts that the relative frequency of ownership of any combination of assets will equal the product of the relative frequencies of ownership of single assets that enter into the given combination. Absolute and relative differences between predicted and actual frequencies of holding various combinations of assets are presented in tables and the differences are submitted to "t" tests. The tests are applied to frequencies of ownership of 12 classes of assets and one debt class. Differences between predicted and actual frequencies are small, and, with few exceptions, the null hypothesis is accepted. Five rejections involve common stock. The tests of the hypothesis are carried out at an aggregative level, but the procedure is equivalent to a more direct microeconomic test using dummy variables for asset holdings and fitting least-squares regressions.

In a model of portfolio selection the author provides a plausible explanation for the lack of substitution effects. The model postulates: (1) many diverse motivations for saving; (2) assets which have many different characteristics in differing degrees; and (3) consumers who differ in their knowledge of and experience with different forms of assets. Thus two consumers may satisfy common motives with different portfolios, and a single portfolio may satisfy differing motives for two holders. The model suggests that the complex network of motivations, characteristics of assets, and perceptions of assets could produce an aggregate distribution of assets with no interdependence between individual assets.

A second major part of the book seeks an explanation of differences among consumers in the proportion of wealth held in assets which vary in money value (shares of stock, real estate, equity in unincorporated business). The major effects discovered were those associated with total assets, age of the head of the consumer unit, self-employment, home ownership, size of the consumer unit, and reported saving for a major purchase.

The analysis of portfolios in terms of fixed versus variable money-valued assets is related to the independence hypothesis only indirectly in that the

two analyses have a common motivational framework, Lewin's field theory. The relationship could be more direct, as Claycamp suggests, in other studies of portfolio structure. While independence between assets may exist at the extreme of disaggregation of wealth posited in Claycamp's study, interdependence of assets may exist at other levels of disaggregation, e.g., between assets with fixed as opposed to variable money values.

Claycamp correctly suggests that the independence hypothesis merits further testing. It is indeed a provocative hypothesis and additional supportive tests could establish a fairly well-defined static equilibrium position for consumers' portfolios. The forthcoming results of the Federal Reserve Board's 1963 Survey of Families' Financial Characteristics will be an excellent body of data for such tests. Other data are already available. The hypothesis does not imply that "in specification of the factors influencing the demand for a given asset, the interaction of that asset with other assets can be disregarded" (p. 29)—not if we are concerned with changes in the amounts held. If, in fact, the changes in assets were independent, the task of explaining total saving on a disaggregated basis would be greatly simplified. The flows of assets would be additive and it would no longer be necessary to lead respondents in financial surveys through tedious details of many assets.

*The Composition of Consumer Savings Portfolios* is the third of a series published under the sponsorship of the Inter-University Committee for Research on Consumer Behavior. The data used in the study were obtained in several sample surveys of a panel of households in two major metropolitan areas. The sample was designed primarily to seek methods of validating consumers' reports of asset holdings and respondents were selected from lists provided by cooperating financial institutions. The sample therefore does not represent a familiar universe, but it is appropriate for the questions posed. The data used are perhaps unique in that they were corrected for errors revealed in the validation process and are relatively free of the response errors that plague surveys of consumers' wealth. Claycamp has tested skillfully a new, and possibly significant, hypothesis about consumer behavior.

HAROLD W. GUTHRIE

*University of Illinois*

*Commercial Bank Loan and Investment Policy.* By DONALD R. HODGMAN. Champaign: Bureau of Economic and Business Research, University of Illinois, 1963. Pp. 181.

"The primary objective of this study," Professor Hodgman states in his introduction, "is to describe and analyze the habitual procedures, criteria of judgment, and attitudes of commercial banks as they make decisions concerning loan and investment policy." An understanding of the manner in which these decisions are made is important in contributing to our knowledge of the working of monetary policy.

The study is based on intensive interviews with the senior management in 18 commercial banks in Chicago, New York, and San Francisco. A comprehensive questionnaire served as the basis for and guide to these interviews.

Financial support was provided by the Merrill Foundation and by the bureaus of business research at the University of California and the University of Illinois. The 12 chapters in the volume cover such topics as loan and investment policies, commercial bank liquidity needs, attitudes towards capital adequacy, customer relationships, and the implications of the findings for public policy.

Based on a careful study of banking practices, policies, and attitudes, the study represents a pioneer work and makes an important contribution to our knowledge of credit and monetary processes. It stands in refreshing contrast to those studies of monetary and credit policy, constructed on hypothetical models which do credit to the vivid imaginations of the progenitors, but which do not reflect actual practices.

A considerable part of the study is concerned with the loan policies of commercial banks. The author finds that banks generally try to forecast both deposit fluctuations and loan requirements. Some employ sources and uses of funds analyses, some rely on area projections of personal income, some base aggregate forecasts on the individual forecasts of bank officers, some try an "intuitive" approach. Loan and deposit forecasts are important, even though the forecasts may prove erroneous, in compelling a bank to consider all of the factors involved in the determination of its liquidity requirements.

In periods of monetary restraint, when banks must select certain loans in preference to others, Hodgman finds that they give priority to commercial and industrial loans. The reason is that these loans not only carry important deposit relationships but have other ancillary advantages. Commercial loans, to be sure, do not afford the highest net interest return. This is obtained from repair and modernization loans extended to individuals, from retail automobile installment paper, and from installment cash loans. In evaluating the attractiveness of separate commercial loans, the author finds that banks give emphasis, in descending order, to the deposit relationship of the borrower, to his credit standing, to the type and marketability of collateral if any is to be offered, to the prospect of continued satisfactory customer relationships, to the rate of interest, to the purpose of the loan, and to the liquidity of the credit. The rate of interest which the borrower is willing to pay is by no means the most important of the desirable criteria.

In a period of credit restraint, commercial banks are not apt to curtail loans to those borrowers who have a satisfactory deposit relationship. Restraint falls on loans lacking this relationship, such as broker's loans, mortgage warehousing and real estate participations, loans to finance companies, certain term loans, etc. The reason that a policy of monetary restraint falls on loans not having a good deposit relationship, is that bank earnings, in so far as the individual bank is concerned, depend upon the deposit and not the loan potential.

When limits must be set to the over-all loan volume, commercial banks rely on loan-deposit ratios, although many banks declared that there is no magic in a particular ratio. Much depends upon the composition and quality of the loan and deposit volume. Banks, however, wish to keep in step with other

banks and do not like their own ratios to deviate greatly from the mode. The author finds that commercial banks ordinarily do not put limits on commercial loans but do so on consumer credit and real estate loans. Some banks relate the total volume of their real estate loans to time deposits, though many banks have not given careful consideration to the problem of relating maturity of assets to the maturity of liabilities.

The author does not look upon the loan portfolio as a source of liquidity, making the point that loan repayment is a source of liquidity for deposit withdrawals but not for loan expansion. True though this be, loan repayment does enable a bank to extend new loans and to maintain the loan volume. Loan turnover can be a very important factor in portfolio policy.

Changes in security prices, he finds, have an important effect, although not a readily determinable one, upon bank policy. If a bank decides to sell securities at a loss, it must weigh the tax advantages of such sales and the future earnings to be derived from the employment of the funds received against the effect of the loss on capital values. Depending upon all attendant circumstances, the "locked-in" effect may or may not be important.

In discussing interbank competition, the author points out that banks provide a unique and specialized service. There is product differentiation among banks as among manufacturing concerns. The prime rate which came into existence during the Great Depression has had the effect, he concludes, of reducing competition.

The requirement of compensating balances also has the effect of limiting interbank competition. It was not enforced in the decade of the 'thirties and was reintroduced in the 'fifties as a means of cementing deposit relationships and of raising interest charges.

By way of conclusion, the author states that the basic services of banks are the safekeeping and transfer of money. It is the increase in deposits which, from the point of view of the individual bank, permits a rise in loans and investments. This means that depositors and not borrowers are the crucial customers of banks. Policies of credit restraint have their impact on the non-depositor (save as it is ameliorated by extensions of trade credit on the part of depositor borrowers). Restrictive credit policy exercises restraint not so much through a rise in interest rates as through a downright refusal to lend. The conclusion is an important one and is receiving increased attention in analyses of credit and monetary policy.

*Poughkeepsie, New York*

### Public Finance: Fiscal Policy

*Federal Tax Treatment of State and Local Securities.* By DAVID J. OTT AND ALLAN H. MELTZER. Washington: Brookings Institution, 1963. Pp. xiv, 346. \$3.00; paper, \$2.00.

This is the second volume to be published in the Brookings program of Studies of Government Finance, a major undertaking in the field of public finance, supported by the Ford Foundation. The book consists of a back-

ground paper (seven-eighths of the volume) for a conference held at Brookings in January, 1962, plus a summary of the discussion at the conference itself. The conferees were about equally divided between people who are involved in the municipals market on either the borrowing or underwriting-investing side and researchers not affiliated with market participants.

The exemption of interest payments on state and local government securities from federal income taxation has survived intact despite a good many assaults throughout the history of the income tax. Its survival, however, has never led to any signs of acquiescence by economists. Traditionally, the major ground for criticism has been the obvious and substantial adverse impact on interpersonal equity in the income tax structure. More recently, the attack has shifted somewhat; along with the general trends in public finance, much of the emphasis is now on the relative inefficiency of the subsidy to state and local governments which tax exemption of interest constitutes. Analysis of the relative efficiency of the device requires quantification, which is inherently worthwhile, since public finance hardly suffers from a superfluity of quantitative analysis. Moreover, emphasis on efficiency generates respectable economic arguments on behalf of the exemption for the first time in its history.

The principal efficiency argument has been that the interest costs saved by state and local governments through the lower yields permitted by the tax exemption are substantially less than the revenue foregone by the federal government. Or, as Roland Robinson concluded in his study, *The Post-war Market for State and Local Government Securities* (National Bureau of Economic Research, 1960), during the postwar period, an increasing share of the revenue loss has accrued to investors in state and local securities, rather than the borrowing governments, who are presumably the intended beneficiaries. A major explanation for such findings is, of course, the special capital market context for the argument. By and large, in recent years, the classes of investors experiencing the most rapid increases in investable funds have been institutions not fully exposed to federal income taxation—pension funds, life insurance companies, and savings institutions—and thus not strongly attracted by tax-exempt securities. Wealthy individuals, commercial banks, and stock nonlife insurance companies, with a considerable interest in tax shelters, have had much more modest growth rates as direct investors in securities.

The Ott and Meltzer study concerns itself largely with efficiency questions, although a wide range of other economic issues is noted in the book. Its major contribution is a new appraisal of the magnitude of the yield differential stemming from the tax exemption, the interest savings of state and local governments, and the revenue losses to the Treasury.

The analysis is careful and comprehensive and goes well beyond the various previous estimates by taking into account—often, necessarily, in a very rough fashion or under stated but reasonable limiting assumptions—a whole range of factors that complicate matters. For example, in dealing with the yield differential, the authors face up to the problem of comparing tax-exempt yields with yields on privately placed corporates, as well as open market yields. Characteristics peculiar to state and local bond issues are not over-

looked: the prevalence of serial, rather than term bonds; the typical steep yield curve within a single offering; the distinctive coupon/offering yield relationships. In estimating the revenue loss to the Treasury, the authors do so on the basis of explicit conclusions as to the shifts of holdings among investor classes that would occur if the tax exemption were removed (which affect the applicable marginal tax rates) and with attention to the consequences of differential tax treatment of capital gains.

The authors conclude, and the findings seem entirely reasonable, that long-term municipals issued in 1960 would have sold for an average of 1.2 to 2.0 per cent more than they did, if not for the tax exemption, an increase in interest costs of 31 to 54 per cent. Over the life of the 1960 issues, state and local agencies would have paid \$1 billion to \$1.8 billion more in interest than they will in fact pay. In contrast, since the weighted marginal tax rate applicable to holders of municipals, were they fully taxable, is estimated at 41-43 per cent, federal revenues (at 1960 rates) would increase by \$1.7 billion to \$1.8 billion under the minimum estimate of the yield differential, and \$2.1 billion to \$2.2 billion under the maximum estimate. By this standard, the tax exemption is inefficient indeed.

The most obvious flaw in the argument to this reviewer—and it is not an overwhelming problem—is the authors' rather ready acceptance of parallelism in the quality ratings of corporate and municipal bonds in estimating the yield differential. The rating systems for municipals involve a fair amount of Doomsday reasoning: if there is a national economic disaster of sufficient magnitude for defaults on general obligation municipals to occur, however wildly improbable this may be, which issue is likely to go under first? In actual fact, the risk of default on lower-rated general obligation municipals may be nonexistent, while the risk of default on equally-rated corporates (for example, railroad bonds) is very real. Thus, a Baa municipal may be equal in riskiness to an A or Aa corporate, and the appropriate yield differential for lower-rated issues may be a good deal smaller than Ott and Meltzer conclude. This, of course, would reinforce their conclusions on the inefficiency of the tax exemption.

Where municipals are low-rated, or not rated at all, because of the small size and unfamiliarity of the borrower, there could, however, be an illiquidity or information cost premium embedded in their yields. Moreover, to the extent that the obligations of small borrowers are not really marketed at all, but placed on a negotiated basis with local investors, the appropriate interest rate comparison in the absence of tax exemption might be with small business borrowing, rather than with the debt obligations of large but risky corporations, implying very high interest costs indeed. For such borrowers, the price of removing the tax exemption might well be some sort of federal marketing assistance, noted by the authors, to encourage large institutional investors in effect to reduce the information and illiquidity costs of the small issues by application of the insurance principle.

*Fiscal Policy for Growth Without Inflation: The German Experiment.* By FREDERICK G. REUSS. Baltimore, Md.: The Johns Hopkins Press, 1963. Pp. xiv, 319. \$7.50.

The mechanisms underlying the striking postwar recovery of the German economy are not what they seem if one relies on eulogies from the financial press in this country or official speeches here and abroad. Chancellor Erhard himself continually emphasizes the *laissez-faire* virtues of the German "free market economy." However, Frederick Reuss suggests that "The hand that rules Germany is definitely not the invisible hand of Adam Smith, nor is it the heavy hand of the socialist planner. It is rather the smooth and hidden hand of a sophisticated and efficient government administration" (p. 28). The operation of this smooth and hidden hand through extensive and detailed manipulations of tax and expenditure policy is impressively and interestingly described by Reuss. In fact, the work is a comprehensive treatise on public finance in Germany and should directly interest students in this area as well as those concerned with economic development.

Because of this comprehensiveness, the reviewer can at best only indicate the general nature of what Reuss describes in detail with the help of extensive statistical tables on every aspect of fiscal policy. When the German monetary reform of 1948 made economic recovery possible, the German authorities found a disorganized economy with heavy unemployment, inadequate financial institutions for intermediation in the savings-investment process, and a generation of individuals whose saving incentives had been destroyed by their memories of two virtually total inflations. In addition, the occupation authorities had imposed a highly progressive corporate and personal income tax system to redistribute income. The new German government started by giving large, ranging down to complete, tax exemptions to individuals and firms who saved and/or invested funds in "acceptable" ways such as for capital goods or housing. The income tax structure was gradually eroded to a complicated tax on particular kinds of expenditures which fell heaviest on current consumption. Subsidies were also used. To take one of many possible examples, income placed in a savings and loan institution and kept there for a period of five years or more was exempted entirely from the income tax. Since this provision was of much more benefit to the wealthy than to the poor saver, in 1959 it was replaced by a straight nontaxable subsidy of 20 per cent of the amount saved, i.e., the effective interest rate on savings deposits rose by 4 per cent. For other forms of saving associated with housing and construction expenditures there remains an option between accepting subsidies or tax exemptions. Total saving in Germany (including that of the government) has been about 21 per cent of the Net National Product.

Besides giving very strong incentives to individuals and firms to save and invest, the federal German government has also acted as a financial intermediary by buying directly the securities of individual firms, undertaking direct government investments, and guaranteeing private bonds to private buyers. The great bulk of such government purchases was financed by current

income so that some 40 per cent of net saving in the economy occurred directly in the public sector in 1960, an increase from 29 per cent in 1950. Thus, this massive intervention by the government is not merely a temporary phenomenon associated with postwar recovery. The fact that government-owned or controlled enterprises are reinvesting profits at higher percentage rates than their private equivalents has led to an increasing share of industrial production accounted for by government-controlled enterprises. For example, in 1959 the government's share was 36.3 per cent in iron mining, 72.2 per cent in aluminum production, and 20.8 per cent in shipbuilding, although the government's heaviest direct investments have been in buildings. This concentration of economic power with the government has made (paradoxically) the German opposition Socialist Party uneasy and was a factor in the sale of the Volkswagen Corporation to private individuals. However, the concentration of economic power with the government remains very high and the complex web of interlocking power shared by government and private industrialists remains a serious social problem in Reuss' view.

Although the German fiscal system is generally considered to be a net success, one could never claim that it satisfies the basic textbook canons of neutrality, equity, and administrative simplicity. Tax exemption of current profits and income used for investment gives tremendous incentives for rapid growth to existing agglomerations of wealth; Reuss strongly suggests that the income distribution in the economy has become more skewed. Transactions taxes which now bring in more revenue than the personal and corporate income taxes (largely because of erosion of the latter two) are certainly regressive and have the further dubious distinction of being largely gross value rather than value-added taxes. Thus, they give significant economic advantages to large vertically integrated corporations. Reuss gives the example that "the tax percentage in the final retail price of men's clothing was estimated at 15.2 per cent for nonintegrated enterprises and 9.1 per cent for integrated enterprises" (p. 130). From an equity point of view, the tax burden is regressive and falls largely on the middle class, although this does not mean that German income distribution is necessarily "worse" than others. In fact, a thoroughgoing German social security system protects individuals at the lower levels of income, something the U.S. system does not do, thus making the equity of the two income distributions rather noncomparable.

A system of special exemptions dependent on the personal position of the taxpayer for the transactions or turnover tax has also grown up, which is administratively complicated like the income tax. This administrative complexity is compounded by a constitution which is unclear in the tax authority granted to the three levels of German government, resulting in shared and divided tax administrations. However, Reuss suggests that this divided authority has permitted effective power to shift increasingly to the federal government, a process which a number of court decisions in favor of the central government has accelerated. It appears remarkable that such a complicated fiscal system does work effectively in the face of these constitutional difficulties.

Throughout the comprehensive descriptive materials in the text, Reuss offers many explanatory and related hypotheses, most of which are insightful, but some could be improved by a more careful development of their analytical basis. For example, he suggests (p. 24) that an inflationary policy in Germany would have been politically and economically untenable because "... the terms of trade would soon have become adverse through inflation. . . ." He repeatedly stresses, and I believe correctly, that a simple Keynesian solution to the very heavy German unemployment in 1948 of simply turning on the tap of aggregate demand would have been entirely inappropriate. The degree of economic disorganization at that time was very great and the aggregate supply of goods and services would have been extremely inelastic in response to demand changes, as he indicates. Thus the policy of deliberately discouraging consumption and directly giving vigorous incentives to build productive capacity was the right one. However, given the present "mature" state of the German economy with great productive capacity and a high volume of personal savings, the Keynesian ideas of policing only the effective level of final demand to control employment and inflation become more appropriate. In fact the direct detailed manipulation of individual taxes is becoming less efficient because of the great erosion of the tax base and more objectionable in its income distribution effects. The incentives to reinvest profits in the same enterprise for the tax advantages greatly handicaps effective monetary policy, as Reuss points out. It is to be hoped that the German authorities do not become so enamoured with the success of their earlier policies that they fail to take into account these changed conditions.

*Federal Fiscal Policy in the Postwar Recessions.* By WILFRED LEWIS, JR.  
Washington, D.C.: The Brookings Institution, 1962. Pp. xv, 311. \$6.75.

This is a case study written in the meticulous detail one expects in works in the institutional or historical tradition of political economy. As appropriate as this approach may be, the treatment of a sequence of events over a somewhat short time span detailing day-to-day policy statements and rearranging statistical data, usually regarded from the same angle, does not make necessarily engrossing reading. That Lewis' book shows few of the latter shortcomings, and probably none for those especially interested in a documented account of the period, can be attributed to his familiarity with the material necessary to describe the recent history of federal compensatory finance. This familiarity has allowed him to chronicle events of the period 1948 to 1962, but with a surprising reluctance to assign economic cause to effect except when referring to fiscal stabilization. He provides an arrangement, however, which is most helpful for readers with differing interests in this apparently new variety of economic recessions.

Chapters 1 to 3 are an empirical examination of the effectiveness of built-in fiscal stabilizers. Chapters 4 to 7 form a second section in which the au-

thor devotes some 180-odd pages to an historical description of the fiscal actions in the four recessions since World War II. Four appendices of statistical computations will be of interest to readers who share Lewis' field of specialization. The bulk of the book can, however, be read with gain by any educated layman.

Although Lewis' monograph is empirical in its nature, there is a theory underlying the policy measures he describes. The same policy objectives, however, could stem from a partly different theoretical substructure that would require a different empirical investigation. As Lewis states, and maintains throughout the book, "... this study presumes agreement with ... the general proposition that the federal government ... use its fiscal powers to combat unemployment ... " (p. 2). In other words, Lewis in accord with one school of thought is primarily interested in the fiscal effects on aggregate demand as manifested through changes in national income. As much as I agree with the "general proposition," I think that the analysis is limited because the fiscal effects on aggregate supply are neglected throughout. I except the possible brief reference (p. 257) where tax credits for business investment are mentioned and other occasional references to business incentives and public works—all tending to increase the productivity of the economic resources of the United States.

In the first part, analyzing the built-in stabilizers, Lewis proceeds to define his strategic "Implicit Federal Surplus" (federal receipts and expenditures calculated at present rates and programs for high employment levels) and to evaluate the fiscal effectiveness of the major federal tax-revenue and expenditure categories in relation to this "surplus." Lewis finds that the corporation income tax ranks high in this respect; the individual income tax shows a small yield flexibility; and, neglecting others, the excise taxes show a high degree of cyclical sensitivity. As one would expect, unemployment compensation payments "constitute by far the most important built-in stabilizer on the expenditure side ... " (p. 57). When turning to the "economic significance" of built-in stabilizers (for Lewis, expressed in their "operation when incomes decline ... " [p. 65]), the author devises a useful classification of direct and indirect stabilizers according to whether or not they affect personal income and thus consumption. It may be worth noting that Lewis' observations confirm the theory that the indirect stabilizers (e.g., corporate income tax) primarily affect retained corporate profits, which in themselves are an important built-in private stabilizer. After a partly digressive discussion of the liquidity effects of the lags in cash receipts, the author concludes that "the combined effect of the various stabilizers has been a substantial source of stability" and that they "are well timed to counteract contraction" but (as in theory recognized long ago) they "also retard recovery ... " (p. 89).

The second part of Lewis' study is related to the political economy of compensatory finance. This again demonstrates most of the well-known constraints and practical shortcomings of anticyclical fiscal policy. If the intertemporal comparisons made possible by this book could be supplemented with some international comparisons, much might be gained. Certainly it

would be found that also outside the United States "discretionary actions" have usually been coincidentally correct rather than in fact wisely "discretionary." But some experiences seem to be historically related uniquely to the United States in her present situation. I may mention two: the role that military expenditures play in relation to the budget and the over-all performance of the economy (see particularly pp. 142, 167, 192, 274) and, second, the overwhelming temptation of presidential candidates—as distinguished from party leaders in a parliamentary democracy—to include in their "platforms" statements related not only to the allocational and distributional aspects of government finance but to economic stabilization as well. Executive fiscal action might be less hampered if commitments of this sort were less specific.

There is a final question. Though the book informs one of many aspects of fiscal policy in the postwar United States, state finance is suspiciously neglected. Were the budgetary activities of all the states at all times fiscally neutral from 1948 to 1962?

*Fiscal Adjustment and Economic Development: A Case Study of Nova Scotia.* By JOHN F. GRAHAM. Toronto: University of Toronto Press, 1963. Pp. xviii, 278. \$6.50.

This book is the first of a series of Atlantic Province Studies. It provides (a) a survey and analysis of the economic position of Nova Scotia which will be of particular interest to Canadians, and (b) a theory of intergovernmental fiscal relations which will be of general interest to students of public finance. The former portion is competent and informative. Nova Scotia is a low-income province because of poor natural resources and geographical location. But John Graham makes sensible suggestions for more effective use of resources in order to accelerate economic development. High priority is assigned to improvement of educational training at all levels.

The theory of intergovernmental fiscal relations from which this book starts was presented and debated more than a decade ago by James M. Buchanan and A. D. Scott. Buchanan advanced as a principle of fiscal equity that the net impact of government should be the same for similar persons, no matter where they lived. Implementation would call for intergovernmental transfers to offset movement of people and resources out of low-income areas. In a low-income province taxes would be higher and/or governmental services less adequate than in a high-income one. An outflow of resources would result unless transfers, especially by grants-in-aid, are made by government from high-income areas. Scott argued that such transfers would be distorting. They would interfere with migration of labor, especially labor of low productivity, to areas where productivity would be higher.

The Buchanan-Scott debate was concerned with federal-state (provincial) levels of government, and so also is Graham. But he explores application of the principle of fiscal equity at the provincial-municipal level. Some idea of

what would be required by the principle of fiscal equity is provided by the following quotation (pp. 42-43):

If federal grants to a province were sufficient to provide revenues which, along with its own provincial and municipal revenues, would enable it to provide about the same level of services as in other provinces, and if provincial and municipal taxes in the different provinces were similar in nature and levied at about the same rates, fiscal equity could be said to be approximated in that a resident of any province would receive about the same fiscal treatment as a similarly situated resident in any other province.

With respect to application of the principle between the nation and Nova Scotia, Graham believes that Scott's generalizations are applicable and Buchanan's inapplicable. Movement of labor and capital out of the province is needed, and increased large federal transfers to Nova Scotia would impede this out-migration, especially of labor. Reluctance to move is strong; the "unproductive," low-income worker is often content to live on unemployment benefits, rather than to migrate.

But application of the principle of fiscal equity *within* the province, Graham concludes, has merit. The provincial government should assume full financial and administrative responsibility for certain general services; it should enlarge its system of conditional and unconditional grants to local governments, the grants being framed so as to be equalizing. To the objection that such a program would be so centralizing as to endanger the vitality of local governments, Graham replies that, for poor local governments, autonomy is barren without the financial means to provide public services at levels comparable to those of wealthy localities.

This reviewer hopes that Graham will continue his research in the field of intergovernmental financial relations. His book contains a profusion of ideas which need more detailed analysis, particularly with respect to the overwhelming practical difficulties in applying fiscal equity at both the interprovincial and intraprovincial levels.

### International Economics

*The Natural Resource Content of United States Foreign Trade 1870-1955.*

By JAROSLAV VANEK. Cambridge: The Massachusetts Institute of Technology Press, 1963. Pp. xvi, 142. \$4.00.

This short but difficult book, a revision of a doctoral dissertation submitted to M.I.T., represents one of the all-too-rare attempts to join the pure theory of international trade with an empirical investigation. Jaroslav Vanek starts with the hypothesis that the "natural resource" content of U.S. net exports has declined substantially over the last century. His principal explanation, following the tradition of Ohlin, is that factor proportions in the United States have shifted away from natural resources toward labor and capital.

Roughly half the book is devoted to the confirmation of Vanek's hypothesis by the facts. "Resource products"—raw materials and crude foodstuffs—have accounted for a steadily declining share of U.S. exports and a generally rising proportion of U.S. imports over the period 1870-1955. In the last century, the United States was a large net exporter of resource products; by the 1950's it was a heavy net importer of resource products. Using input-output techniques, Vanek shows that the same general trend is observed even when the indirect component of resource products in foreign trade is taken into account—presumably laying to rest the possibility that U.S. exports continue to be concentrated on heavy resource-using products, only in a slightly more fabricated form. The downward trend is much less marked in the case of "renewable" resource products—indeed it is questionable whether any downward trend exists at all during the last 30 years—than it is for nonrenewable (mineral) products.

The remainder of the book provides a theoretical explanation for this marked change. Vanek emphasizes the change in factor proportions in the United States: a rapid growth in population and an even more rapid growth in capital, relative to the growth in labor forces and capital stocks abroad, shifted the comparative advantage of the United States away from resource-using products. The shift in factor proportions was further extended by an actual fall in the supply of nonrenewable resources as they were used up. Rapidly rising factor productivity in the mining industries offset partly—but not fully—the adverse shift in factor proportions; but the growth in agricultural productivity over the whole period lagged behind productivity growth in manufacturing, thus reinforcing the shift in factor proportions away from agriculture.

Vanek was hampered at every stage by the unavailability of data that would fit precisely his theoretical concepts—or by the failure of the theory to lend itself to easy empirical application. He was forced to compromise at many points and made a free and imaginative use of simplifying assumptions and proxy variables. His most important compromise was the substitution of the share in foreign trade of "resource products"—products "making direct use of natural resources"—for the natural resource (pure rent) content in all exports and imports. Practical data considerations made some such substitution necessary, but it leaves the reader with less than full confidence in the empirical results. The boundary between "crude foodstuffs" (resource products in Vanek's study) and "manufactured foodstuffs" (nonresource products) is an arbitrary one, and while the former have risen in relation to total U.S. imports over Vanek's period, the latter have fallen. Taking a somewhat different approach to the measurement of resource scarcity in the United States, Barnett and Morse found in *Scarcity and Growth* that advancing technology has kept pace with the "depletion" of natural resources. Their data show that net U.S. imports of minerals maintained a roughly constant share of U.S. consumption of raw materials in the period 1870-1940, although a sharp rise (due largely to petroleum) has occurred since then. Vanek's hypothesis would imply a rising share throughout.

The changing factor-proportion explanation for the shifting composition of U.S. trade can be reversed for the past decade and possibly for the next. High postwar rates of investment abroad, especially in the other developed countries, could be expected to shift U.S. comparative advantage back toward resource-using products, particularly in view of the very rapid postwar growth in U.S. agricultural productivity. Recent changes in the commodity composition of U.S. trade are therefore consistent with Vanek's thesis.

Vanek concludes his book with two provocative observations:

1. The Malthusian pressure of population against limited resources has not occurred because many countries remain underdeveloped, and hence their demand for natural resources remains low. Had these countries developed with Europe and America over the 19th century, the price of natural resources would have risen relative to other prices. Thus, argues Vanek, it is easy to understand the concern of many Westerners about the "population explosion" engendered by economic development; it will raise the relative price of resources and thereby hurt the present industrial countries.

2. Because owners of natural resources generally have short time horizons, social costs of natural resources exceed private costs. As a result, the underdeveloped countries, as net exporters of natural resources, have been transferring wealth to the industrial countries—just the opposite of what most would agree is the proper direction for transfer.

The first of these observations is at least questionable. True, more widespread and earlier industrialization would have raised greatly the demand for natural resources. But as Schmookler has suggested, invention and discovery are positively related to economic activity. More widespread industrialization would have greatly increased the number of inventors and innovators—the size of the research and development "industry"—and the greater talent devoted to finding cost-reducing techniques might have kept up with the rising demand for resources.

The second point, if correct, provides a persuasive rationale for the increasing practice of taxing production and export of natural resources.

Apart from the necessarily detailed discussion of data and assumptions which make difficult reading, the book unfortunately suffers from poor arrangement and occasional redundancy. And the empirical discussion has important deficiencies; practically nothing is said, for example, about changing factor proportions abroad; yet Vanek's explanation hinges on a change in factor proportions in the United States *relative* to those abroad. Moreover, such exclusive attention is paid to changing factor proportions in the United States that not even passing mention is given to many other factors that affected the observations, such as the inability of Europe and Japan to supply nonresource goods in the immediate postwar period. This inability biased postwar U.S. imports toward resource products. From 1953-55, when Vanek's observations end, to 1960-62, finished manufactures rose from 22 per cent to 36 per cent of total U.S. imports, while foodstuffs and crude materials together fell from 54 per cent to 44 per cent.

Individual parts are better than the book as a whole, however; Chapter 3,

for instance, offers an excellent theoretical discussion of the effects of growth on trade.

RICHARD N. COOPER

*Yale University*

*Price and Quantity Trends in the Foreign Trade of the United States.* Studies in International Economic Relations, No. 2. By ROBERT E. LIPSEY. Princeton: Princeton University Press for National Bureau of Economic Research, 1963. Pp. xviii, 487. \$10.00.

This volume, like many other NBER studies, performs a dual function: first, presentation and description of new basic data in the form of annual and quarterly price and quantity indexes for U.S. exports and imports (Chs. 3-6, Appendixes A-F); and secondly, initial exploitation of the analytical implications of the trends revealed by the new annual data (Chs. 1-2, Appendixes G-H). Each function merits separate attention.

The principal statistical product is a reasonably consistent series of price and quantity indexes and dollar values for total exports and imports and five major economic classes of exports and imports for the years 1879-1960. New indexes were actually constructed only for the years 1879-1923, for a decision was made to accept the official Department of Commerce series for the period after 1923 and to concentrate on the earlier years for which the data were less reliable, not broken down by commodity groups, and heavily over-weighted with primary products. This decision can be justified on grounds of reliability and cost-savings; however, it also implies acceptance of the existing classification system, which ignores differences between "productivity-oriented" and "natural-resource-oriented" finished manufactures and obscures thereby certain major trends in trade.

For the years 1879-1923, furthermore, annual Fisher price and quantity indexes and dollar values are published for 22 export classes and 23 import classes as well as for selected intermediate and minor classes. In addition, there are presented for 12 selected major classes annual Paasche and Laspeyres price indexes, quarterly Fisher price and quantity indexes, and quarterly dollar values. All the indexes were constructed in four segments: 1913-23, 1899-1913, 1889-99, and 1879-89, using the final year of each as base so as to obtain the benefits of improving statistical coverage. Interpolative quarterly series are included to fill the gap between 1923 and 1929 (when the quarterly Department of Commerce series begin).

The description of the new indexes reflects the meticulous standards which we have come to associate with the NBER. There is detailed consideration of such questions as the measurement of sampling errors, measures of coverage and changes in coverage, the quality of the underlying trade data, and the problems of weighting bias. Particularly noteworthy is the decision to publish some underlying Paasche and Laspeyres indexes. Comparison of these series not only serves the technical purpose of facilitating judgment as to whether apparent differences between American and foreign indexes "rep-

resent real differences in behavior or only the results of comparing dissimilar types of index number" (p. 83), but also serves the broader purpose of helping to eliminate such vestiges of elasticity pessimism as may remain among economists.

Turning to the second or analytical function, one is impressed by new evidence of the *cumulative* additions to knowledge being provided by the NBER statistical studies. Robert Lipsey, for example, combines his price data with Kendrick's indexes of output per man-hour and total factor productivity to construct two series of the single factorial terms of trade; these exhibit some fourfold improvement over the period covered. More significantly, he combines his quantity data with Shaw's commodity output and Kuznets' GNP series to demonstrate that the U.S. trade-output ratio has now returned to the level of the 1880's after a long period of decline. Lipsey offers a careful analysis of the various factors that have contributed to shifts in this ratio. But the present reviewer might have been tempted to push the interpretation of the data a step further and advance the hypothesis that, for the United States, declines in the trade-output ratio occur during periods of rapid economic growth relative to the rest of the world, while increases in this ratio take place when the comparative U.S. growth rate is low.

The author separates his analysis of trends in prices and the terms of trade from his treatment of trends in values and quantities. This reviewer found the latter much more informative and original. Not only does the investigation of values and quantities include a thoughtful exposition of the theoretical implications of changes in the trade-output ratio, but it also provides an excellent analysis of the role of agriculture and farm exports in nineteenth-century growth and a highly imaginative discussion of differences between long-term and short-term patterns of price-quantity behavior. Shifts in supply functions are treated as being essentially long-term and yielding negative price-quantity relationships, while changes in demand functions are considered mainly short-term and are associated with positive price-quantity relationships.

The particular emphasis used by Lipsey in his interpretation of the price-trend data is best revealed in his own words:

Two widely held beliefs regarding net barter terms of trade find no confirmation in the data for the United States. One is that there has been a substantial long-term improvement in the terms of trade of developed countries, including the United States; the other, that there has been a significant long-term deterioration in the terms of trade of primary as compared to manufactured products" (p. 76).

This interpretation seems to be based on a common misconception of the nature of the terms-of-trade hypotheses advanced in the literature (a misconception shared by most proponents of such hypotheses). As persuasively if not conclusively demonstrated by Nurkse in the case of low-income economies, the terms-of-trade hypotheses should be interpreted as *ex ante* rather than *ex post* arguments because the law of supply and demand must be presumed to work in the long run: Changes in the terms of trade, by inducing

"shifts in production and in the distribution of resources, are apt to be washed out in the long run"—with the result that, for economies which are characterized by a limited capacity to transform, what may be a "terms-of-trade problem in the medium run" becomes a "development problem in the long run."<sup>1</sup>

In the light of the significant degree of transformation capacity which has characterized the U.S. economy, the chances of terms-of-trade movements being washed out in the long run would appear to be considerably larger than in the case of underdeveloped countries. Analytical emphasis should have been placed, therefore, not on the inherently truistic statistical developments, but on the mechanism of adjustment through which the secular constancy of the terms of trade was achieved. Lipsey's own data and analytical subconclusions are in themselves quite useful in explaining the nature of the adjustment mechanism for the United States. There was, for example, the growing industrial transformation of the economy which is reflected in the fact that "the behavior of U.S. terms of trade, independent of or even inverse to that of Europe before 1920, became quite similar after that date" (pp. 14-15). Furthermore, the conflicting trends in trade between agricultural and manufactured products are revealing of the unique quality lent to developments by the considerable diversity of the U.S. economy itself; between the 1880's and the 1950's there simultaneously took place a "great decline in the ratio of export prices to import prices for manufactured goods" and a "large increase in the ratio of export prices to import prices among agricultural products" (p. 20).

Beyond this difference regarding the interpretation that should be given to terms-of-trade hypotheses, this reviewer found Lipsey's analysis to be sound, imaginative, and quite stimulating to his own thinking. The underlying statistical series themselves, of course, constitute an indispensable tool in the kit of any economist who wishes to deal seriously with U.S. trade problems.

EUGENE R. SCHLESINGER

*New York University*

<sup>1</sup> Ragnar Nurkse, *Equilibrium and Growth in the World Economy*, Cambridge 1961, p. 334.

*The Communist Foreign Trade System.* By FREDERICK L. PRYOR. Cambridge: Massachusetts Institute of Technology Press, 1963. Pp. 296. \$7.50.

As the author notes in the preface to this study, "academic research on the Communist bloc presents particular difficulties. . . ." In his case, these "difficulties" included six months of imprisonment in East Berlin. The academic initiative so harshly rewarded included a series of interviews with East German foreign trade officials. The material provided by these interviews helps to make this informative analysis of the Communist foreign trade system a unique source of information and insight into the complicated subject with which it deals. Frederick Pryor's arrest by the East German regime is

highly ironic, since he is less critical of Communist foreign trade policies than are many other Western observers. Much of this book is a vigorous and detailed criticism of bloc foreign trade practices and theory which amply documents past and present inefficiencies. Nevertheless, Pryor presents evidence of increasing information, better theory and gradually improving performance and his over-all judgment is that "the development of the Communist foreign trade system has been impressive."

Throughout the study, Pryor stresses the theoretical inadequacy of bloc analyses of foreign trade problems, and the significance of this shortcoming for policy. Thus: "The split between recognized need [for more, and more profitable, trade] and relative neglect [of foreign trade] lies . . . in the fact that foreign trade planners failed to demonstrate concretely to the top policy-makers the actual trade potentialities" (p. 130). Or, in discussing CEMA's tasks for the future, "First of all, Bloc economists must develop a theory of foreign trade and economic integration and must devise a set of rational criteria to decide the most satisfactory division of labour between the individual nations" (p. 228). Pryor's samples of bloc foreign trade theory, both in this book and in his *Soviet Studies* article on this subject,<sup>1</sup> are appalling examples of theoretical flabbiness resulting, in part, from trying to squeeze theory into a Marxist straightjacket. But Pryor perhaps overemphasizes the relative significance of faulty theory compared to the institutional and political barriers to a more optimal use of bloc resources. Moreover, there is far from complete agreement even in the West on the relationship of trade and development. While the rigid application of a Stalinist model of development in each nation of Eastern Europe clearly leads to gross absurdities, what is the optimal degree of specialization? Pryor concludes that: "The concern for large-scale industrialization in every Bloc country, although often buttressed by some incorrect autarkist theories, is certainly valid" (p. 229). I think he would agree that an adequate theoretical formulation of "this concern for large-scale industrialization" would not be easily come by.

Pryor, of course, recognizes the difficulty of building an adequate theory of foreign trade when the elementary construction material—prices, costs, exchange rates, etc.—is shoddy and unreliable. An inconvertible world where prices are arbitrary, costs unclear, and exchange rates misleading is not a world where an optimal trade pattern is likely to be arrived at—good theory or no. Where even the struggle for feasibility is fierce, the cause of optimality must inevitably be a lost one. And Pryor's documentation of the battle to fit foreign trade into the planning process is one of the major virtues of this volume. However, he attempts to show that the significance of one institutional barrier often cited by Western observers—the barrier of bilateralism—has been greatly exaggerated. Such a conclusion is a novel one and, if sustained, would call for the withdrawal of one of the major criticisms of the Communist foreign trade system.

Pryor's major piece of evidence is an index of multilateralism—relating the absolute value of bilateral imbalances to total trade turnover—which

<sup>1</sup> "Foreign Trade Theory in the Communist Bloc," *Soviet Studies*, July 1962.

shows little difference between the Common Market and the European Soviet bloc in degree of multilateralism. As Pryor recognizes, this index is difficult to use for comparative purposes: identical indices of multilateralism for the EEC and CEMA could well reflect vastly different degrees of departure from a free trade equilibrium. Moreover, Michael Michaely's September 1962 article in this journal on "Multilateral Balancing in International Trade," which Pryor cites but was not able to take fully into account, shows that of the 65 nations in his study, the five Soviet bloc nations have the lowest degrees of multilateralism. And in each case the degree of multilateralism sharply drops between 1938 (or 1948) and 1958. Before accepting Pryor's conclusions, these results would have to be explained.

More fundamentally, the benefits of multilateralism are not to be found in mechanically totting up bilateral imbalances. What is significant is the freedom a multilateral system allows to use credits with one country or group of countries to offset debits with others. Even a system of huge bilateral imbalances where no multilateral clearing is permitted would approximate the optimal multilateral solution only by the sheerest chance. Pryor notes that some intrabloc arrangements have been made for shifting trade balances but also agrees that these arrangements have been clumsy and difficult to work out. The contention that the present clearing bank has not been given greater powers because the need for multilateralism "did not impress the Bloc policymakers enough to make any radical changes" is unconvincing. Isn't it more likely that the practical and theoretical difficulties that would arise from attempting to establish a multilateral system within a bloc of planned economies are simply too knotty to be easily overcome?

Theoretical and institutional obstacles to a rational bloc division of labor are accompanied, as in the West, by political obstacles. Pryor's remarks on these problems are brief but sensible. Hitherto docile Rumania's sudden and successful display of intransigence last spring suggests that they are no less pronounced in Eastern than in Western Europe. The Rumanian episode also focuses attention once again on the issue of Soviet economic dominance. Could Rumania really turn to the West if CEMA continued to press forward vigorously with its original plans of economic integration? By insisting on developing her own industrial base is not Rumania tightening the bonds which tie her to the USSR? One issue which quickly arises from speculations of this sort is that of alleged Soviet exploitation of her East European allies. Pryor demonstrates the statistical difficulties involved in documenting this contention. In particular, he points out that whereas the terms of trade of the USSR with other bloc nations were more favorable than those with the West, this was also true for every other bloc country. This does not mean that there is no discrimination, rather that there may be mutual discrimination, the net effect of which is difficult to estimate. Thus, Pryor finds that trade bargaining among socialist countries is no less spirited than among capitalist countries and concludes that "Although Bloc trade officials played sweet tunes of proletarian internationalism in public, they practiced price discrimination in private."

Pryor's study ranges over a wide variety of other issues—East-West trade, CEMA's operations, foreign-trade criteria, intrabloc price setting, foreign-trade monopolies in Communist countries—and many others. In general, his discussion of these issues is informed and enlightening. However, he is perhaps too conscientious in trying to mine the available statistics for material to support his conclusions. Readers of this study will be well advised to check carefully the underpinnings of Pryor's tabular and statistical material to assess for themselves its reliability and significance. But if this study suggests more than it proves, this is all that can be reasonably expected, given the information available and the complexity of the problems discussed. Moreover, the subject of Communist foreign trade seems to lend itself to heated partisan controversy; this book, however, is a serious and scholarly study, essentially unbiased in tone and approach. For students of Communist foreign trade, this is an indispensable volume.

CHARLES A. COOPER

*The RAND Corporation*

*Trade Blocs and Common Markets.* By SIDNEY DELL. New York: Alfred A. Knopf, 1963. Pp. xviii, 375, x. \$5.95.

It has been rather common to regard the recent emergence of the European Common Market as a revolutionary but wholly beneficial development in world affairs. The study by Sidney Dell, however, very forcibly amends this impression by an appeal to common logic and by use of uncommonly concise historical analysis. Here it is shown that the formation of EEC is yet another reaction to world economic trends where economic groupings are constantly emerging to correct excessive economic forces of other areas. The world economy is viewed almost as an organism of regional growth and contraction, of conflict and collaboration, and of constant regrouping and reorganizing.

The challenge is clearly made in the book that free trade is hardly the basic aim of regional groupings of nations. More exactly, and in correct historical perspective, the aim of most regional groupings, especially those of common markets, is seen as an attempt to establish preserves of economic endeavor shielded by protective barriers.

The main objective of this book is to examine origins of the numerous common markets emerging in different parts of the world and, incidentally, to reveal the patterns of national and regional interaction. Recent regional developments both in Europe and in other continents are comprehensively examined. It has not been the author's purpose to present the free trade case but rather to set down instances of its denial and of lip service paid to it.

The chief conclusions of the book are that the newest element in regional evolution is the merging of industrial giants on a geographical basis and a grouping of new nations which were former dependencies of the industrial powers. For the present the EEC has emerged as the strongest and most advanced of the regional groupings. As a reaction the regional groupings of underdeveloped countries appear as an eventual and even necessary step. The

EEC is seen both as a rival and ally of the United States. Stress is given to the view that common markets do not merely unite; they divide as well.

Although economic advantage is seen as the motive for historical development, the author finds little economic advantage to the new groupings of nations. Economies of mass production have been largely realized in the industrial countries, and there are no strong economic ties among the underdeveloped countries. Nevertheless, attention is directed towards the intensification of competition, the possibility of a withdrawal of government in the field of regulation, and a weakening of the labor unions in the new integrated complex. The consequence is a strengthening of the larger business concerns, a prospect which has inspired fears in labor circles in the United Kingdom and elsewhere.

The case of the underdeveloped countries is strongly and objectively put by Dell. Trade restrictions appear as a means for regulating the growth of underdeveloped countries. The perversity of international economic policy is such that restrictions are oddly combined with increased amounts of foreign aid. The underdeveloped countries in their present state of fragmentation have little hope of economic viability and little power in bargaining for reductions in tariffs against their commodities.

In some respects Dell has gone too far with his method of analysis. In his search for origins of trade groupings he uses the exclusive test of free trade versus protectionism. He sees no middle ground between the extremes of free trade and protectionism. He does not enlighten us on how we could measure a free trade or a protectionist economic policy. The economic union of the states of the United States and the confederation of the German states during the nineteenth century are not, for this reviewer, completely analogous to the current developments in the common market. German policy during the 1930's and parallel movements in Japan with its aim of a "greater co-prosperity sphere" are drawn too heavily in economic terms. Reliance on the forces of economic materialism makes Dell see too much in the economic factors involved in colonialism, whether it be the old colonialism of the seventeenth and eighteenth centuries, the imperialistic brand of colonialism of the nineteenth century, or neocolonialism in the twentieth century as seen in Yankee imperialism, international economic capitalism, or the more recent and more widespread types of Soviet colonialism.

In stressing tariffs and protectionism other policies and activities of government tend to be overlooked. Tax policy and banking policy as well as military and social policies tend to be underplayed as contributing factors. For example, in considering U.S. tariff history Dell overlooks the instances where tariffs were necessitated by the impossibility of acquiring revenue through income taxes and other devices. This also happens to be a difficulty for governments in underdeveloped countries searching for tax revenues at the present time.

On the whole this book is a refreshing review of recent regional economic developments on a broad plane of analysis. The relevance of EEC in an economic world of transition is thoroughly examined. The author does not ignore

the conflicts within the Community or those created outside of the Community. Attention to the problems of underdeveloped countries gives a balance of viewpoint absent in many other works dealing with common markets or *the* Common Market. This book is worthy of close reading by all those interested in international economic problems.

**Business Finance; Investment and Security Markets; Insurance**

*A Study of Mutual Funds.* By I. FRIEND, F. E. BROWN, E. S. HERMAN, AND D. VICKERS. Prepared for the Securities and Exchange Commission by the Securities Research Unit, Wharton School of Finance and Commerce, University of Pennsylvania. Report of the House Committee on Interstate and Foreign Commerce, 87th Congress, 2nd session. Washington: Superintendent of Documents, 1962. Pp. xxxiii, 595.

One may sardonically observe that the "Soaring Sixties" is thus far an apt description of economic developments for which the term was coined. However, it is good strategy to put a nonearning asset to some profitable use. The term, "Soaring Sixties," can justifiably be used to describe the number of investigations and reports that have been produced on the operations of the financial system in the United States.

Despite their plethora, there have been no major indictments emanating from these studies. These reports may therefore bewilder the owners and managers of institutions comprising the financial system, who understandably wonder why all these studies were necessary in the absence of any major difficulties. On the other hand, one might observe that financial institutions—among the most regulated enterprises in the United States—have often had the regulations pertaining to their operations dictated by the aftermath of emergencies or crises. As such, the patchwork of regulation that has grown up has often been retrospective, attempting to cure past ills rather than prospective.

The present rash of reports and recommendations has one virtue at least. The reports are the products of an era of no demonstrated flagrant abuses in the financial community and no critical shortcomings in the performance of financial institutions. In this reviewer's judgment there is a virtue to a continuous surveillance and responsible investigation and reporting of findings on the operations of the financial system. For the consequences of the performance of this function, assuming it is responsibly discharged, will be to provide for an evolving set of regulations which corrects abuses before they become excessive and dangerous to the stability of the economy as well as ensuring opportunities for adjusting the regulations, either statutory or administrative, to the present and foreseeable needs and requirements of the economy.

In August, 1962, the Chairman of the Securities and Exchange Commission transmitted *A Study of Mutual Funds* to the Chairman of the House Committee on Interstate and Foreign Commerce, under whose imprint it was

published. The study was undertaken pursuant to Section 14B of the Investment Company Act of 1940, which authorizes the Commission from time to time "to make a study and investigation of the effects of size on the investment policy of investment companies and on security markets, on concentration of control of wealth and industry and on companies in which investment companies are interested. . . ."

Conforming with this authority, the Commission engaged the Wharton School to make a fact-finding survey of "certain aspects and practices of open-end investment companies or mutual funds." The *Study* was produced by four members of the faculty of the Wharton School of Finance and Commerce: Irwin Friend, F. E. Brown, Edward S. Herman, and Douglas Vickers. The completed manuscript is a massive document consisting of 595 small-print pages including 273 tables, exclusive of subtables distributed among these numbered tables. This publication represents the first extensive description and analysis of the growth of the mutual fund industry since the earlier SEC *Report on Investment Trust and Investment Companies* published from 1939 through 1942.

The coverage of the report is reflected in the titles of its chapters: Chapter 1 is a "Summary and Conclusion"; Chapter 2, the "Structure and Control of Open-End Investment Companies"; Chapter 3, "Mutual Fund Growth 1952-1958"; Chapter 4, "Investment Policy"; Chapter 5, "Investment Company Performance"; Chapter 6, "Impact of Investment Funds on the Stock Market"; Chapter 7, "Open-End Investment Companies and Portfolio Company Control"; Chapter 8, "Investment Advisors of Open-End Investment Companies."

Out of the welter of material included in this study, five general topics will be singled out for comment. These are (1) a description of the mutual fund industry; (2) the effect of size on concentration of control within the industry and the degree of control over portfolio companies by mutual funds; (3) the impact of the industry on the stock market; (4) the performance of the mutual fund industry; and finally, (5) potential conflicts of interest that may arise in the mutual fund business.

(1) Students of finance will be in debt to the authors of the Wharton School *Study* for a long time. The extensive data relating to the anatomy of the mutual fund industry, its structure, growth, and control are exceedingly informative. The material on the size characteristics of firms in the industry, the fund inflows, and share turnover supply us with a wealth of detail. Some of the most useful information is the detailed examination of investment policy in Chapter IV. Portfolio distribution classified in a number of ways, the mechanism of portfolio transactions, and data on portfolio turnover all serve as a prelude to a discussion of the response of mutual funds as investors to movements in the prices of securities. This material should enrich the literature of portfolio policy and asset choices which is rapidly becoming an important subject in monetary economics.

(2) The authors of the Investment Company Act were clearly motivated by two long-standing concerns of public policy in this country. The first of

these is the almost ingrained fear of size and concentration which is a pervasive element in public policy prescription not only in the finance business but in the whole area of competitive policy for industry. However, this fear of size is compounded by a second concern which has a long history in the United States, namely, concentration of control over economic activity by financial firms through their holdings of corporate securities. Since mutual funds hold largely equities, hence potential voting power over managements of (portfolio) companies, it is easy to perceive the thread of concern in the 1940 Act that concentration of control in the mutual fund industry provides a possible avenue for concentration of control over all economic activity in this country.

On the first of these issues, the authors report "One general conclusion . . . is that the main problems affecting mutual funds do not seem to relate to the size of individual funds or companies but rather to the industry as a whole. This is not to say that size of individual funds may not be a problem at some time in the future but simply that there is little evidence it is one at the present or that it is any more of a problem currently than it had been earlier" (p. 3; see also p. 78). The authors then go on to say "The most important current problems appear to be those which involve potential conflicts of interest between fund management and shareowners, the possible absence of arm's-length bargaining between fund management and investment advisors, and the impact of fund growth and stock purchases on stock prices. But these problems are not related to company size except in the sense that questions arise about the distribution between fund shareowners and investment advisors of benefits resulting from large-scale operations" (pp. 3-4).

With respect to the possibility of abuse arising from control over portfolio companies, the Wharton School *Study* concludes: "Despite the growth of large holdings of mutual funds, outright control of portfolio companies by these organizations is a rarity and is confined mainly to small companies as envisaged by the authors of the act of 1940. Mutual funds with large holdings undoubtedly exercise varying degrees of influence with portfolio companies, but as of late 1958 neither the extent nor character of their influence appear to be such as to warrant serious concern" (p. 26).

(3) In attempting to assess the impact of mutual fund activity on stock prices, the *Study* attempted to ascertain the relationship during 1953-58 between fund purchases and the level of market and individual stock prices over varying periods of time. The authors show a wholesome respect for the difficulties of this task (pp. 360-63).

Despite the general inconclusiveness of their tests, the Wharton group concludes that "it seems likely that the growth in the funds' net purchases of common stock has stimulated stock prices markedly during the past decade or so, during which the industry has expanded enormously" (pp. 21, 359).

In buttressing this argument, which is based partly on their statistical analysis and partly on a priori reasoning, the authors appear to argue that a substantial portion of the money invested in the funds and hence in the equity markets is secured from saving that is not traditionally channeled into the

stock market. Until and unless we have better information on household savings habits the findings of the *Study* will continue to be the proper subject of debate.<sup>1</sup> In my opinion the authors have suggested some pieces of evidence which add to our knowledge of this subject, although the evidence is hardly conclusive.

(4) The aforementioned findings were received with relative calm or complete indifference. However, the assessment of the mutual funds' performance created a furor. The *Study* concluded: "For the 5¾ years covered . . . , the Standard & Poor's Composite Common Stock Index was definitely superior to the average performance of the funds, but the disparity can be explained by the portfolio structure of the funds; i.e., the division of their portfolios among common stock, preferred stock, corporate bonds, government securities and other assets. When adjustments are made for this composition, the average performance by the funds did not differ appreciably from what would have been achieved by an unmanaged portfolio with the same division among asset types. About half the funds performed better, half worse, than such an unmanaged portfolio" (pp. 17-18).

The performance of a hypothetical "unmanaged portfolio" does not reflect the costs and resources required to reproduce every change in composition reflected in the market averages. In addition the authors say "since perhaps the major function effectively served by mutual funds is the provision of diversification, a feature particularly important to small investors who can ill afford large risks, it is important to point out that such an investor who attempted to achieve a comparable degree of diversification by direct purchases might incur acquisition costs in excess of the 8 per cent charge typically imposed by the funds."

Testing the performance of the investment company industry is a complex and difficult task (pp. 289-94). The Wharton group proceeds on the assumption that performance is properly measured by the results realized from holding a portfolio over time. Because they are interested in performance and not investor experience (pp. 289-90), they sought out an index of the securities market as a whole to enable them to make comparisons of the results of investment companies to external securities market standards (pp. 293 ff.).

They define a performance index as the ratio of end-of-year net assets, dividends, and distributed profits per share to net assets per share at the beginning of the year. This measure is then applied annually to a population of 152 mutual funds. To arrive at a cumulative performance, an index was calculated. The resulting performance figure shows that the growth of the 152 investment funds was 96.7 per cent from 1953 to 1956. This performance index was then compared with the cumulative growth rate of a weighted average of the various Standard & Poor's security indices. The weights were derived from the percentage distribution of assets held by the mutual funds. This weighted average had grown by 98.2 per cent during the 5¾ years.

<sup>1</sup> In a subsequent study the authors offer some corroborative evidence for the position that a substantial portion of money invested in funds would not have otherwise been channeled into the stock market. See *SEC Report of Special Study of Securities Markets*, Part IV, Ch. 11, Appendix XI-A-II, p. 358.

Farrar has put forth an alternative test of performance.<sup>2</sup> He has shown that if the desirability of portfolios is judged according to their rate of return and risk (price variance) then the various classes of mutual funds hold nearly optimum portfolios. Thus one can optimize a portfolio *at a given moment of time* in the light of the *past* average returns and variance of the securities irrespective of whether they were held or were just acquired.

It is clear that the Wharton study rejects this definition of performance. In this reviewer's judgment these views need not be alternatives but complementary. For an investor should be interested both in what the fund accomplished in the past and in what it is currently holding.

(5) The report points up the separation of ownership and control in the mutual fund industry. Since this phenomenon is now recognized as a fact of corporate economic life, one is led to the conclusion that mutual funds are, in this respect, like most other corporations. And mutual fund shareholders like other shareholders can evince their displeasure with managers by parting with their shares.

Further aspects of the structure of the industry, the nature of competition and possible conflicts of interest between the fund, its advisors, and its shareholders are discussed in the final chapter. The fees that investment advisory concerns charge mutual funds tend to be higher than those charged by the same advisors to other clients. The Wharton group argues that owing to economies of scale, the expenses involved in advising mutual funds were less than those incurred in advising other clients.

The report further finds that mutual funds pay their advisors an annual fee of approximately  $\frac{1}{2}$  per cent of the annual average of net assets. Since sales of funds' shares have been a means of expanding their assets and such increases produce increases in the absolute fees collected by the advisor, a prospective conflict of interest arises between a mutual fund's shareholders and the fund's investment advisor with respect to selling efforts.

Other possible conflicts of interest were also noted. Among those advisors interviewed approximately 40 per cent were affiliated with brokerage houses and 95 per cent with underwriting firms. The implication is that portfolio churning may be profitable for the advisors in their major business efforts rather than in the discharge of their advisory function for the funds.

On the assumption that entry is free and competition among funds is present, it is not immediately clear what action is required by the findings in this section. On the matter of entry, it is noteworthy that 37 new firms came into being over the period 1952-58 (p. 77). As to the existence of competition within the industry, the *Study's* summary concludes:

Competition among mutual funds has provided investors with a wide range of choice as to fund type, loading charge, etc. It has stimulated efforts to achieve outstanding investment performance since fund sales, at least to some extent, have been positively correlated with fund performance. Competition in promoting sales directly as well as indirectly through winning and stimulating dealer sales efforts with respect to par-

<sup>2</sup> D. E. Farrar, *The Investment Decision Under Uncertainty*, Englewood Cliffs, N.J., 1962, *passim*.

ticular funds has been an important characteristic of the mutual fund industry. Thus competition in the mutual fund business has assumed the principal nonprice forms—variety of product, product quality, and sales promotion—but for the most part it has involved price, at the investor level, only insofar as size of sales charge has become a competition factor as between the principal funds in the industry and the no-load companies, which still constitute a relatively small fringe of the business. Management fee rates and the allocation of brokerage business have not as yet elicited important competitive responses for a major part of the industry (p. 35).

Apparently the presence of nonprice competition is disturbing to the authors of the report. But in the absence of collusion it is difficult to argue vigorously for changes in the present regulations in this industry. In addition to the struggle for the saver's dollar that is at work within the mutual fund industry, other forms of competition also exist. Presumably a saver interested in acquiring variable priced assets may do so on his own.

It should be mentioned, however, that an alternative interpretation of the report's findings is its expressed concern over possible monopoly power based on lack of knowledge (including alternative sources) available to savers.

The *Study* should serve to stimulate changes in the mutual fund industry. This reviewer's interpretation is that the *Study* suggests that more efficient operations should enable firms to compete effectively with existing practices. Alternatively, the description of the industry should serve as an open invitation to either new firms or new practices, which should reduce costs of operation and increase returns to savers. If the analysis of the structure and efficiency of the industry as outlined in the *Study* is correct, one likely outcome will be alteration of practices or increases in the number of firms, either of which should redound to the public's advantage.

In conclusion, while this reviewer has suggested possible points of difference with the findings of the report, it is his studied opinion that the Wharton School group has provided the raw materials for continuous studies in the mutual fund industry. The concern over some current practices in the industry should heighten public interest in the conduct of the affairs of mutual fund companies. The public is in debt to this group for a careful and searching scrutiny. Undoubtedly some conclusions will be discarded as a result of a careful and scholarly examination of the findings by others. However, when the smoke of battle dies down, the industry will probably be the better for the report—a view which is undoubtedly not well received by the industry at present.

*Trends in the Distribution of Stock Ownership.* By E. B. Cox. Philadelphia: University of Pennsylvania Press, 1963. Pp. xiii, 221. \$6.00.

Growth in the distribution of stock ownership has received widespread publicity in recent years. It has led some to "the heartening conclusion" that

"a quiet economic revolution is reshaping America" and that "America can be a society composed of many millions of private capitalists." These are comments made by Keith Funston in his introduction to the 1959 census of shareowners by the New York Stock Exchange and the idea has gained wide acceptance. Therefore, it is startling to read in Professor Cox's "Trends in the Distribution of Stock Ownership" that in 1959 one out of eight adults owned stock, or approximately the same proportion of the population as in 1930! The 1962 Stock Exchange census is not included in Professor Cox's study, but doubt is not dispelled by a further rise in ownership to one out of six adults. That survey was made early in 1962, since which time there have been signs of a general public withdrawal from the stock market following the sharp decline in stock prices in May and June of that year.

It is a fair guess, therefore, that stock ownership is still not significantly broader than it was at the height of the stock market boom in 1929. In the interim, the number of stockholders dropped sharply and then recovered. From ten million in 1930, the number declined to about five million in 1950. It is the growth since 1950 which appears so impressive until it is related to the previous decline and to the growth in population. Viewed in this light, the expansion in the number of stockholders to 12.5 million in 1959 and 17 million in 1962 is probably at least as much a cyclical movement as a resumption of the long term growth trend that raised the number from 1 million in 1900 to 10 million in 1930. It is too bad that so little has been done in this area to separate the cyclical variations from the trend.

Cyclical variations in this context need mean nothing more specific than the ebb and flow of public interest in common stocks. From the earliest experiences in the Mississippi and South Sea bubbles, there have been recurrences of intense public interest in stocks by hordes of people who are not ordinarily investors in such securities. They are people who are attracted not for reasons of safety or income, but in the hope of quick profit. When profits cease to accrue—as happens sooner or later—they lose interest and return to the safety and income of bonds and savings accounts. How much of the recent growth in the number of stockholders may have been due to speculation by newcomers who leave the market when prices drop is a moot point. Signs of public withdrawal from the market since the price decline in the middle of 1962, however, are numerous. They include brokerage reports of reduced activity on the part of the small "investor," the sharp drop in sales of mutual funds accompanied by a record rate of redemptions, and the drastic decline in the sale of new issues of common stock. Coupled with these are a sharp rise in time deposits and a flood of advertising for savings accounts.

The usefulness of Cox's work is primarily the historical perspective in which he has placed the data on stock ownership. He has done this efficiently, tracing the studies from the earliest ones by Warshaw in 1924 through Berle and Means' extension of those figures and the TNEC report in the late 1930's. Then he takes up the postwar period and the more extensive studies, mostly by the New York Stock Exchange. He recognizes the vast difficulties in obtaining reliable information when ownership is so often lodged in that faceless creature, the nominee. But his effort to expand our knowledge by means

of a questionnaire sent to some 80 companies is not very helpful. Nor do the isolated company surveys of their own stockholders add much. For determining the numbers and characteristics of stockholders the broad sampling techniques, such as those used in the Stock Exchange surveys, will probably continue to be the main source of this kind of information.

What is not to be found in the material which Cox reviews is a thorough analysis of the trends in stock ownership as between individuals and institutions and the trends among the institutions themselves. (The Stock Exchange specifically excludes from its surveys the holdings of all nonindividual stockholders.) Those who work closely with securities are acutely aware of the enormous impact on common stocks from the phenomenal growth of pension funds and their tendency to put increasing portions of their assets into stocks during the 1950's. Information on the holdings of pension funds, mutual funds, insurance companies and other institutional investors should be more valuable than data showing that individuals who own stock have better than average incomes, education, and liquid assets; that they tend to be older persons, and that they come from the professional, managerial, or entrepreneurial occupations.

Finally, there is a set of data which should be integrated into any study on stock ownership. These are the little-publicized figures of the SEC on the dollar amounts of stock added to or subtracted from their holdings by individuals. They appear quarterly under the heading "Savings by Individuals in the United States." For several years now, these figures have provided a sharp contrast to the rapid growth in the number of stockholders, for they show a persistent and growing tendency for individuals as a group to dispose of stock. Beginning with a net reduction of \$.3 billion in 1958, the reduction was \$.9 billion in 1959, \$1.9 billion in 1960, \$2.2 billion in 1961 and \$3.5 billion in 1962. For each of the first two quarters of 1963 the reduction was \$.8 billion, or very nearly the same rate as in 1962. Presumably the few are giving up stock even faster than the many are acquiring it, the difference being made up by institutions. Surely these figures bear some import and merit consideration in a study of stock ownership.

SIMEON HUTNER

*Princeton, New Jersey*

*The Life Insurance Enterprise, 1885-1910: A Study in the Limits of Corporate Power.* By MORTON KELLER. Cambridge: Belknap Press of Harvard University Press, 1963. Pp. x, 338. \$7.25.

Scholars familiar with life insurance history have long been impressed by the importance of the Armstrong investigation of 1905 in bringing about a much needed reform in the operation of American life companies, especially the five industry giants domiciled in the New York City area. The author of this well-written and well-documented monograph does not question the significance of the Armstrong investigation for the subsequent history of the industry. He does, however, point out that the managements of the big five were under growing pressure from internal forces prior to 1905 to reform their

policies and practices. Yet progress in this direction was slow, with the result that "the Armstrong investigation focused the concern of an aroused community, exposed the already shaky structure of the societies to public view, and stimulated a profound evolution in their corporate being" (p. 292).

This book unquestionably puts the events affecting American life insurance during the critical period from the mid-1880's to 1910 into clearer historical perspective. As a case study, it also substantiates the conclusion of the author that to the traditional sum of external checks on corporate power in a free society, as outlined by Galbraith and others, should be added "the complex but significant factor of internal restraints: the problems and consequences inherent in the processes of institutional growth and maturity."

*Soviet Marketing—Distribution in a Controlled Economy.* By MARSHALL I. GOLDMAN. New York: The Free Press of Glencoe, 1963. Pp. vii, 229. \$5.95.

This volume provides an up-to-date account of institutional and organizational aspects of the distribution of consumers' goods in the USSR. Successive chapters describe: (1) the distribution networks and the administrative apparatus under which each operates; (2) planning and pricing procedures, given the allocation of resources between consumption and nonconsumption; and (3) the system of financial controls exercised by the state, and especially by the State Bank, over the marketing operation. No such recent account is available elsewhere in English, and here lies a primary value of the study.

How well, how efficiently, does the distribution system work? In sections of the institutional chapters and in one separate chapter, Professor Goldman considers the responsiveness of the system to consumers' preferences and the response of the system to the tests of performance and incentive in force, and he finds notable inadequacies and inefficiencies in both respects. This discussion exemplifies for a particular sector the kinds of problems of economic organization that other students of the Soviet economy have pointed to more generally.

A concluding chapter inquires into the role of marketing in a controlled economy. Goldman emphasizes that the USSR has now reached a stage of development at which the level of real income is sufficiently high to yield familiar problems in the production and distribution of consumers' goods, quite apart from the Soviet institutions involved. Because incomes have risen, choices proliferate and demand becomes a variable that is both influential and subject to influence. Everything produced is not automatically sold. The marketing function expands from the elementary activities of packaging, storing, and transporting to research and merchandising. Thus, Goldman observes recent complaints in the Soviet press about excessive inventor-

ies and the occurrence of various merchandising developments: price reductions on goods in excess supply; the expansion of advertising and product differentiation; the introduction of installment credit for certain durables; the creation of wholesale agencies which organize trade fairs and circulate information on stocks and requirements in trade. The prediction is that as incomes continue to rise Soviet marketing practices will tend to resemble more and more those of the capitalist West.

Without questioning that prediction, I wonder whether additional attention should not be given to other possible developments. From recent Soviet discussions of the role and power of the Soviet firm, can one foresee changes that would increase the firm's responsiveness to consumer preferences? From the new Soviet interest in the application of mathematics to economics—apparently including models relevant to demand estimation<sup>1</sup>—can one foresee the introduction of large-scale econometric models for planning purposes?

Finally, there is an empirical chapter on distribution costs. For 1960 Goldman calculates the ratio of the distribution markup (retail and wholesale distribution costs plus profit) to retail sales. The result—20 to 30 per cent, depending on some component estimates—is compared with the U.S. markup-to-sales ratios of 37-50 per cent and with the official Soviet claim that retail and wholesale distribution costs are only 7.5 per cent of retail sales. The calculated ratio differs from the official ratio mainly because the official ratio includes turnover taxes in the denominator, excludes profits and the costs of procurement from the numerator, and excludes collective farm market sales and costs.

Goldman also compares retail sales per worker in the USSR and the United States by applying average ruble-dollar price ratios to sales per worker in native currencies. The calculation is repeated for 1954 and 1958, with USSR and U.S. weights, and for sales-per-worker data of varying scope. In rubles, sales per worker in the USSR tend to be about 80 per cent of those in the United States; in dollars, the ratio is greater and, for some calculations, greater than unity.<sup>2</sup> For reasons with which I tend to agree, Goldman is reluctant to make much of any of these international comparisons as efficiency comparisons. Although this reluctance may explain the somewhat casual character of the comparisons, it is not clear why he has bothered with them here at all.

NORMAN M. KAPLAN

*University of Rochester*

<sup>1</sup> E.g., A. Agranbegan *et al.*, *Primenenie matematiki i elektronnoi tekhniki v planirovanii*, Moscow 1961, Section III.

<sup>2</sup> See Table 18, pp. 180-81. Goldman does not put the results quite in this way. He seems to be unaware that the logic of alternative USSR- and U.S.-weighted price "deflators" is alternative comparisons in rubles and in dollars. It should also be pointed out that (a) the average ruble-dollar ratios he uses include a sizable component of services which do not enter retail sales and which have much lower ruble-dollar ratios than foods and manufactured goods; and (b) although the average ruble-dollar ratios he uses refer to 1954, he uses them without adjustment to "deflate" 1958 as well as 1954 sales data at current prices.

### Industrial Organization; Government and Business; Industry Studies

*The Development of Firms—An Empirical Study with Special Reference to the Economic Effects of Taxation.* By A. S. MACKINTOSH. New York: Cambridge University Press, 1963. Pp. x, 305. \$7.00.

Growth-conscious governments, of which there are many in the modern world, are necessarily much concerned with the factors that limit the development of individual business enterprises. In order to study these factors, and in particular the impact of income taxation on them, Mr. A. S. Mackintosh, now Deputy Director of the British Overseas Development Institute, made in 1955-56 an intensive analysis of the postwar behavior of 36 Birmingham manufacturing firms. The results, which were first made available to the Board of Trade in 1957, have now been published after considerable delay and should be of interest to economists in both the fiscal and the development fields.

The book opens with the exposition of a general theory of business behavior that is both more flexible and less precise than the standard theory of the firm. Taking the basic business goal to be the greatest possible increase in the firm's ability to earn profits over a planning period of five to ten years, Part I briefly describes various means of attaining that goal and then focuses on five factors, called boundary conditions, that can limit the firm's rate of development. These factors are: (1) the amount of finance available to it from various sources; (2) the strength of the ambitions and incentives of its managers; (3) the availability of the factors of production needed for its operations; (4) the expandability of the markets in which it currently sells or to which it can readily shift its attention; and (5) in the absence of any of the above, the maximum rate at which growth can be effectively sustained even under the most favorable conditions. In his sample survey, the nature of which is described in Part II of the book, Mackintosh found that finance was the most frequently encountered of these limitations upon development (14 firms named it as an important restriction), with maximum rate second (9 firms), followed by lack of ambition or incentives (5 firms), factor supplies (5 firms), and market (3 firms).

Finance is also, of course, the one restriction to growth that can be directly eased by a reduction in income taxes, and Mackintosh gives it special attention in Part III, where the survey evidence is analyzed in detail. While the sample used is too restrictive to support general conclusions, three propositions especially suggestive of further research are put forward:

1. There is some profit rate,  $P_1$ , which most firms must achieve over a five to ten year period unless they are to be limited in their growth primarily by lack of finance, and some higher profit rate,  $P_2$ , above which firms are unlikely to be subject to a finance limit. For his sample of businesses Mackintosh estimates  $P_1$  to be  $16\frac{1}{2}$  per cent (profits before taxes divided by net assets) and  $P_2$  to be 22 per cent, regardless of the size of the firm or of the industry in which it operates. The possibility that higher income taxes mainly restrict

investment by low-profit enterprises raises interesting welfare questions which Mackintosh does not discuss.

2. Lower taxation of corporate profits will raise business investment directly by only a small fraction (estimated at 10-33 per cent) of the foregone tax yield, whereas considerably more of the tax saving will be used, particularly by large corporations, to repay outstanding indebtedness, to acquire financial assets, or to pay dividends. If this is so, the indirect effects of tax changes on investment, exerted through financial markets, may be even more important than the direct effects.

3. British investment allowances (subsidies) affected investment decisions in only 25 per cent of the firms studied, and their quantitative impact was small in most cases. Mackintosh regards this result, however, as an underestimate because of the newness of investment allowances (they were introduced only 20 months before the survey interviews were made), and argues strongly for them as growth stimulators in the place of straight tax rate reductions. He is apparently unconcerned about the interpersonal inequities imposed by this policy choice.

Dividend policies and the effects of the use of accelerated depreciation for tax purposes are also discussed in Part III, but the treatment is disappointing in view of the far more satisfactory work done on these topics in the past ten years in the United States (to which no reference is made).

The second half of the book (Part IV) is devoted to an extended analysis of each of the 36 firms studied. This is not a section likely to sustain the interest of the general reader, but the specialist is offered a wealth of information concerning such things as profit rates, sources and uses of funds, investment planning, and price policies. One gets the impression that Birmingham entrepreneurs, with some notable exceptions, are a cautious and conservative lot, and it would be interesting to compare their attitudes and behavior with those of businessmen elsewhere in Britain or in other countries. As other studies of this kind become available, much should be learned about the mysteries of economic growth.

*British Shipping and World Competition.* By S. G. STURMEY. New York: Oxford University Press; London: Athlone Press, University of London, 1962. Pp. x, 436. \$8.00.

Charges of unfair competition through governmental aids to national merchant marine fleets have filled diplomatic dispatches and periodical literature of western European countries in recent years. Government subsidies, flag discrimination, tax aids, and transfers to flags of convenience have been among the leading charges. Particular focus has been given on occasion to the assistance to the U.S. merchant marine through construction and operating subsidies, cargo preference arrangements, and the acceptance of the auxiliary role of U.S. beneficially-owned bulk carriers under Panamanian and Liberian registry.

Are such conditions the explanation for the relative decline in the position of British shipping in the world from 45 per cent in 1900 to about 16 per cent in 1960? This is the question that is probed by S. G. Sturmev of University College, London, in his study. Through historical and economic analysis, he strips away layer by layer the factors that have entered into this decline. At the hard core, he finds decline resulting from the absence of self-evaluation in merchant shipping circles, accompanied by adherence to out-moded patterns of operation in the face of changing requirements.

The supremacy of British shipping in the period from 1850 to 1914 was the product of a unique set of circumstances. These included the primacy of British industrialization, the substantial trade with its colonies, the importance of its domestic coal supply for world bunkering stations and local markets, and the advantage of adequate domestic ship repair facilities and ports. The merchant marine was aided by the practice of British importers and exporters who sought in the terms of sale and purchase to be free to nominate the ships of use, namely British flag ships.

The historic supremacy of British shipping and its economic tie with coal resources are demonstrated by Sturmev to have served as constraining influences for over half a century. The development of oil resources and the diesel engine undermined the competitive advantage which high-grade domestic coal had given British tramps over lower-wage Norwegian and Greek ships. The patterns of ship ownership and operations which developed in the pre-war period remained substantially unchanged. British shipowners did not view tankers as ships, hence missing the opportunity to enter the newly expanding tanker trade in the interwar period. By contrast, the Norwegians were able to make their transition to the requirements of the transport and the utilization of oil. In the crucial period of the twenties, new enterprisers of Norway entered ship operations, gathering capital where they could at home and abroad. They organized themselves as supplementary providers to meet the needs of British and other petroleum companies who were operating a portion of their own ship requirements. The Norwegian practice of using extended time charters with petroleum companies as the basis for construction credits developed then and continued after World War II. Unlike British shipping interests which have continued to separate liner, tramp, tanker and bulk-carrier operations, Norwegian shipping interests fused their operations, thus hedging against cyclical fluctuations and assuring some flexibility in their ship operations.

To the contentions of the British shipping industry that foreign governmental aids in the form of subsidies and flag discrimination have thwarted the retention of the British shipping position, the author develops historical evidence to show that the British position had already been downgraded before subsidization had become extensive. He draws on the Norwegian experience in the 'twenties and the postwar period as evidence that adaptation to changing requirements has been the avenue for substantial and profitable entry into the world market, despite the absence of governmental aid in the form of subsidy and flag discrimination and the absence of a substantial national

trade. He views the subsidized U.S. flag fleet as being substantially circumscribed both in the world shipping market and in U.S. trade. On flags of convenience, the author points out that companies registered abroad may, and do in fact, register their ships under British flags. While established British interests have complained about the development of the Panlibhon registries, the author points out that they actually place the participation of foreign interests in British flag shipping on the credit side of the British shipping industry's ledger. The labor cost factor is dismissed as a cause of decline, for although British shipbuilding costs may be higher than those abroad, seamen's wages are shown to be substantially in line with those of other leading European maritime countries. Labor-management relations are described as having had a company-interest orientation, with labor officials emphasizing their concern for the industry. British law remains unchanged in making no distinction for trade disputes in port for disciplinary purposes. Official strikes have not occurred in the past 30 years. The result has been rank-and-file rebellion on two recent occasions.

Basically, intrinsic conditions are found to account for the decline. In addition to the failure to adapt extensively to diesel engines, there has also been the failure to move with the times with faster and larger ships. There has been the continuing concern with traditional organization in liner and tramp operations, and only recently efforts have been made to explore new opportunities associated with the growth of tankers in world trade. In the tramp area, the author suggests that, in view of the higher wage position of Britain along with the other northern European countries, the need here is for faster, larger ships to compensate for the lower crew costs but older and slower ships operated by Greek shipowners.

The emphasis given by the author to self-evaluation and self-help warrants an observation on the documentation in the study. Despite the importance of British shipping to the national economy and the national image, the British literature cited in the report is relatively thin. The latest official report referred to is dated 1939. The latest shipping industry reports were made in 1939 and 1960. The author indicates that family control of shipping enterprises has resulted in avoidance of public discussion and disclosure. Actually, much of the data relating to British costs is derived from the hearings and reports of U.S. congressional committees on the subsidized merchant marine. In the United States, continuing governmental scrutiny has been the result of defense concern, consideration of the appropriateness of governmental allocations and policy in support of the U.S. flag merchant marine, and flare-ups resulting from union jurisdictional disputes. The role of such governmental concern as goad to industry efforts to meet the challenge of intensified competition through improvements in ship technology, size, and speed warrants study. The analysis and message contained in Sturme's study are obviously needed in Britain, but will prove useful elsewhere.

JOSEPH P. GOLDBERG

*Washington, D.C.*

*The Technology of Urban Transportation.* By DONALD S. BERRY, GEORGE W. BLOMME, PAUL W. SHULDINER AND JOHN H. JONES. Evanston: Northwestern University Press for Transportation Center, Northwestern University, 1963. Pp. xiv, 145.

The sudden rise to prominence of urban planning and the calling forth of economists, sociologists, and other social scientists into service make this little book timely.

With the passage of the 1962 Federal-Aid Highway Act, much of the planning activity at this stage is involved in trying to solve the problems of mobility within the metropolitan complex. In some cities, this has engendered heated arguments over the relative efficiencies of various transportation media.

After a brief survey of highway facilities and operating characteristics of the automobile, there is a good coverage of transit operations and equipment. Despite the glamor of futuristic-appearing rail rapid transit, equal space is given to buses and railroad commuter services. Included are tabulations on transit maintenance and operation costs, motor bus operating speeds on free-ways and exclusive curb lanes, capital outlay requirements on proposed rail rapid transit systems, and possible innovations in urban travel. Much of the material has been sifted out of the copious volumes of data in metropolitan area transportation studies. Other sources are included in their very comprehensive and useful bibliography.

The final section of the book has an excellent comparison of the capabilities of various types of transportation systems. The importance of finding the combination best suited to each area's characteristics of population density, economic development, and land use is stressed rather than reliance on any one mode of travel.

The authors evidently wrote the book with the idea of supplying information on the least-known subjects. It would seem, however, that in presenting a survey of this type, the characteristics of automotive transportation deserve more attention. This leads to a major complaint about the book; it should have been twice as long. Despite its compactness, however, the authors have managed to present a book written with considerable clarity which will appeal to the interested nonspecialist.

### **Land Economics; Agricultural Economics; Economic Geography; Housing**

*Housing and Income.* By MARGARET G. REID. Chicago, Illinois: The University of Chicago Press, 1962. 415 p. \$7.50.

This is a book with a message. This message, which is transmitted with great fervor, contains essentially two parts. First, the permanent income hypothesis of Milton Friedman provides a useful framework for the study of

consumer behavior. (The essence of this hypothesis is that consumer expenditures and savings are determined primarily by long-run, or permanent, income rather than by current income.) The value of this framework becomes apparent when it is used as a basis for the study of consumer demand for housing, which is the subject of this book.

Second, the income elasticity of housing is much larger than has previously been supposed. In particular, the usual highly inelastic income elasticities obtained from analysis of cross-section data with consumer units as the individual observations provide misleadingly low estimates of this elasticity. In other words, Schwabe's "Law of Rent," that the proportion of income spent for housing declines with income level, is not true. Estimates of income elasticity of housing obtained from such cross-section regressions are biased because the principal independent variable is measured income, not "normal," or long-run income. Since families gear their housing expenditures to normal income and not necessarily to current income, the discrepancy between the two variables represents, in effect, an error of measurement, which according to statistical estimation theory is bound to bias downward the estimate of income elasticity. This bias is shown to be substantial, and housing is asserted to be highly income elastic, the true value of the elasticity being in the neighborhood of 2.0.

The basis for this conclusion is the permanent income hypothesis. Miss Reid, following Milton Friedman, represents current, measured, family income as the sum of two components: normal (equivalent to permanent) income and transitory income. Housing expenditure, being of a long-term nature, is asserted to be a function of normal income. Therefore, true income elasticities can only be obtained when the transitory component of income is eliminated from measured income. This she attempts to do, again following Milton Friedman, by combining consumer units into groups which may be expected to have more or less the same level of normal income. Since transitory income for a group of families homogeneous in normal income is, by definition, composed of erratic and more or less random elements, this combination procedure serves to reduce greatly the relative importance of transitory income. As a result, regressions of housing expenditure on income and on other relevant variables for these groups are much more likely to yield true income elasticities than are the usual regressions with the individual family as the unit of observation.

The empirical work that supports this reasoning comprises the bulk of this volume, and rests on a virtually bewildering number and variety of regressions, some of a cross-section nature and others utilizing time series data. Initially, cross-section estimates of income elasticity based on regressions between average income and average housing expenditure by income level are shown to be quite low (Chapter 5). These elasticities are reduced even further if variables are introduced holding constant such variables as occupation, education, race, and urban area. Since these variables are presumably proxies for normal income, their introduction serves to increase the relative importance of transitory income, thereby increasing the bias and reducing

the estimated income elasticity. Estimated income elasticity rises if family size and age of children are introduced into the housing-income regression, these variables presumably serving to increase the importance of normal income.

To get rid of the bias due to the imperfections of measured income and of measured housing, Miss Reid proceeds to estimate the cross-section income elasticity by correlating average income with average housing expenditure, first for cities as a whole (Chapter 6), next for particular strata that would reflect normal income within cities—house quality and Census tract (Chapter 7), and finally by differences in income and housing expenditures between central cities and their suburbs (Chapter 8). These regressions produce a wide variety of income elasticity estimates, ranging from .8 to almost 3.0, but averaging roughly 2.0. It is largely on the basis of these data, which are asserted to be least contaminated with transitory income effects, that Miss Reid concludes that housing expenditures are actually highly income elastic. In the course of doing so, she finds that total expenditures constitute an unsatisfactory proxy for normal income (Chapter 9), which is fortunate because the elasticities thereby obtained tend to be appreciably below unity.

The time series evidence provides less impressive support. Regressing total annual housing expenditures on annual income yields low elasticities for the pre-World War II period, though rising to about 1.4 for the postwar years (Chapter 10). Regressions of temporal changes in housing expenditure on changes in average income and in various other variables, with cities as the unit of observation, yield income elasticities ranging from 1.1 to 2.0 for 1919-1934, but the elasticities are not much above 1.0 for 1918-1950.

In contrast to the preceding material, all of which suggests that the demand for housing is highly elastic, an analysis of the demand for rooms (Chapter 12) yields low elasticities, ranging from .2 to .5. According to Miss Reid, "the difference suggests that it is useful to look upon demand for rooms as relatively inelastic, whereas the demand for quality housing is highly elastic with respect to income" (p. 348). A final empirical chapter (13) presents a brief analysis of data from the 1960 census, suggesting that all of the previous results receive additional support.

The book concludes with two chapters summarizing the principal findings and discussing their implications for public housing programs and for the analysis of consumer behavior. In particular, she emphasizes the potential applicability of the same techniques to other categories of consumer expenditure.

Despite the tremendous amount of painstaking empirical work presented in this volume, the permanent income hypothesis receives much less support than one would expect, considering the exclusive focus of the book on the single most important category of consumer expenditure. From a conceptual point of view, the question of why housing expenditures should be related to "normal income" is ignored, except for a few brief passages in which this relation is accepted as obvious. To be sure, it is intuitively plausible that consumers should gear their housing outlays to some longer-run enabling measure than current income. But do they do so? Can they do so even if

they think in terms of normal income? And, if so, how is normal income estimated? To what extent do biases in these estimates and the presence of uncertainty affect any such planned expenditures?

No discussion or empirical evidence are to be found on such issues. Yet, the very size of housing expenditures suggests that such questions may be far more important for the applicability of the permanent income hypothesis to this category than to any other type of expenditure. To mention a few reasons relating to housing why the hypothesis may need modification: (1) a young couple might not have the financial resources to buy a house commensurate with its level of normal income; (2) because of satisfaction with such facilities, the family may not care to move to more expensive housing even when its income rises to or above its level of normal income; and (3) unavailability of housing at all price levels for minority groups will interfere with the operation of the hypothesis.

The meaning, use, stability, and consistency (among consumer units) of normal income are even more basic questions that might have been considered, although they relate not to housing alone.

Under the circumstances, question may well be raised of the extent to which the empirical results truly support the permanent income hypothesis. Even further question may be raised in the light of the weaknesses of the basic data, particularly with respect to the necessarily arbitrary estimate of housing expenditures of consumer units in owner-occupied dwellings. In such cases, housing expenditure is assumed equivalent to the rental value of the dwelling, which is in turn estimated at 10 per cent of the owner's estimate of its market value. In view of the substantial appreciation of housing prices during the post-World War II period, housing consumption in the sense used in this study may be substantially overstated by the use of rental value, because of offsetting saving in the form of capital appreciation. This is particularly true of the many homes purchased with large mortgages before the fifties, since these mortgages have been paid off with much cheaper dollars. The estimation of rental value as a constant percentage of the value reported for all types of homes raises further questions. Little support is provided for this procedure, and it is hard to believe that any single percentage would provide an unbiased estimate of rental value of all types of homes, in all cities, for all types of people, and in all years.

In view of the conceptual and empirical difficulties encountered in attempting to reconcile the empirical results with the permanent income hypothesis, it is only natural to seek other hypotheses that might also explain these results. No doubt other such hypotheses exist, some stemming from economic considerations while others may stem from the nature of the data themselves. The latter point of view, which has been hardly explored in the past, would seem to suggest at least one such explanation. This explanation relates to the little-known phenomenon of data combination, which, as noted previously, comprises the statistical basis for all of Miss Reid's results. Evidence exists that incomes are understated in consumer surveys and that the extent of understatement may increase with income level, both in absolute and in relative terms. If this is so, housing-income regressions using income

level as the unit of observation will be biased downward substantially, simply because of errors of measurement. On the other hand, if such regressions are computed using cities as the unit of observation—units large enough to permit averaging of errors over all levels of income—the errors in the data are bound to be much less than in the previous case, and the resulting income elasticities will be substantially higher. Thus, these results would support Miss Reid's basic assertion, that housing expenditures are truly income elastic, though not for the reasons cited.

This is not the place to explore the various ramifications of this hypothesis. All things considered, however, it is not at all clear that the results presented in this volume provide strong support for the permanent income hypothesis, even though this hypothesis serves as the framework for the volume. It is clear that Miss Reid has provided us with a highly provocative piece of work, carried out with great care and painstaking detail. Considerable doubt has been shed on the long-held belief in the income-inelastic nature of housing expenditures. This is a major contribution to the study of consumer behavior.

ROBERT FERBER

*University of Illinois*

*Politics and World Oil Economics—An Account of the International Oil Industry in Its Political Environment.* By J. E. HARTSHORN. New York: Praeger Publishing Co., 1962. Pp. 365. \$8.50.

J. E. Hartshorn has addressed himself to a topic which is of vital interest to the Free World and which virtually cries out for a competent economic discussion of its various policy facets. Of all the commodities that flow across national boundaries, probably none is more important than oil for modern economies.

Hartshorn's book is divided into three parts. Part I (about half the book) is an attempt to develop an historic and analytical perspective about the international oil industry. Part II attempts to develop an understanding of the present problems of the industry vis-à-vis the various governments of both the producing and consuming nations. The third and shortest section of the book attempts to assess the future roles of consuming nations, host governments, and the international firms.

The author has described his work as "a descriptive book with some attempt at analysis" (p. 28). Unfortunately both the descriptive and the analytical sections suffer from inaccuracies. Since Hartshorn eschews footnotes, it is impossible to check on the veracity of the many statistical and historical "facts" which fill this volume; however, the glaring inaccuracies and omissions of some obvious facts—e.g., placing Eugene V. Rostow on the Harvard faculty (p. 207), or the omission of any mention of the dumping of "distressed" gasoline by refiners as a factor in U.S. retail gas price wars (pp. 123 ff.)—raise doubts about the accuracy and/or the completeness of all the descriptive portions of the book.

The book's greatest fault, however, lies in its incorrect analytical treatment of the basic supply and demand factors that affect the industry. Instead of

providing the reader with some new analytical insights about the oil industry, Hartshorn tends merely to repeat many of the cliché rationalizations which he has obtained by "asking questions . . . of [unidentified] people inside this industry, or in a position to influence it" (p. 26). This *post hoc ergo propter hoc* analysis, however, which is often used by industry spokesmen to justify the industry's position, simply cannot be accepted at face value. Hartshorn's naïve acceptance of such analysis results in many incorrect statements and leads him to at least one major indefensible conclusion, namely that the international supply of oil is "the same as might be expected to arise from the operation of the law of comparative costs in a freely competitive international market" (p. 340). Had Hartshorn properly analyzed the wealth of evidence available (including much of the descriptive material presented in his book), he might have reached a quite different judgment.

Space limitations prevent a complete cataloguing of all the implicit and explicit analytical errors committed by the author. A few of the more important errors will be suggested below, in the hopes of alerting the reader to the incorrect analytical foundation of Hartshorn's major conclusions, and to suggest, where possible, the proper line of analysis.

Perhaps the most obvious blunder which appears throughout is Hartshorn's confusion about the nature of the economic concepts of marginal and average costs. Despite Hartshorn's endless repetition, it does not automatically follow that since fixed costs are high relative to operating costs, the crude oil segment of the industry is *always* "a situation of 'decreasing marginal costs'" (p. 57). (Declining average total costs do not necessarily imply decreasing marginal costs.) Similarly, the high capital intensity of the refining stage of the industry does not necessarily mean that there are "diminishing costs and increasing returns for each incremental barrel up to the limits of capacity" (p. 69), as Hartshorn claims.<sup>1</sup>

Furthermore, Hartshorn is apparently completely unaware of the ramifications of his belief that the oil industry is one of decreasing marginal costs. He is oblivious to the well-established analytical conclusions that *if* the industry is one of decreasing marginal costs, then (a) competition is incompatible with stability, and (b) such an industry will exhibit a market failure, i.e., it will not efficiently allocate resources if entrepreneurs are motivated by profit maximization in a market system.<sup>2</sup> Accordingly, Hartshorn's conclusion about the efficacy of the logistics of oil under present arrangements (p. 340) is inconsistent with his major (but not necessarily correct)<sup>3</sup> belief that the oil industry is one which exhibits decreasing marginal costs.

Furthermore, Hartshorn's own discussion of the marketing aspects of the international oil industry belies his own belief in the economic efficiency of

<sup>1</sup> Hartshorn's complete lack of understanding of cost concepts can also be found on page 111 where he confuses average variable costs and total variable costs when he claims that low rates of operation raise "total operating expenses." On pages 69-70, Hartshorn incorrectly concludes that one cannot obtain the marginal cost of each product when products are jointly produced in variable proportions.

<sup>2</sup> See F. Bator, "The Anatomy of Market Failure," *Quart. Jour. Econ.*, Aug. 1958, 72, 365-69.

<sup>3</sup> Adelman has presented a strong argument suggesting that (1) a high fixed cost/

the present situation. Hartshorn's constant references to (1) the barriers to entry in world markets (pp. 73, 103-04, 106-07, 112, 144-45), (2) the present surplus of oil (pp. 53, 207), (3) price discrimination practices (pp. 125, 222), (4) basing points (pp. 134-35), (5) the oligopolistic nature of the international market and the parallel interest of the seven major international companies (pp. 155, 159), (6) the ubiquitousness of nonprice competition (pp. 155-56), (7) the improved channels of communication between rival companies as a result of joint ventures (pp. 162-65), and (8) the protective practices of consumer governments for domestic energy industries (pp. 142, 206-07, 248), call attention to the ludicrous nature of his conclusion that "the economic logic of this industry indeed relies upon the concept of the world as a single market, across which resources can freely be traded to the benefit of all; it is one of the few genuinely international manifestations of private enterprise" (p. 167).

Despite the large number of pages (in Part I) that Hartshorn devotes to the discussion of the price of oil, he never correctly analyzes supply and demand factors;<sup>4</sup> rather he tends to discuss supply and demand in the slipshod language of the financial reporter which results in the conclusion that the price is what it is because no one has made it anything else—e.g., see the discussion of the price of Libyan oil (pp. 149-50).

In his discussion of conservation, Hartshorn does provide the reader with an insight as to why, though he peppers his prose with economic jargon, he consistently misuses analytical economic concepts. For example, he gives the correct economic definition of conservation, i.e., "if the discounted future value of oil exceeds the cost of doing without it today, restricting output would be economically logical" (p. 187). He then dismisses such a "purist criteria" [sic] (on the grounds that it involves assessing an uncertain future) and in doing so indicates his distaste for economists since they "are well placed to point out the weaknesses in other people's approaches to questions of conservation, but less competent to follow out the ramifications of their own (a posture some may consider characteristic of the profession)" (p. 188). Such anti-intellectual comments are not likely to advance the public discussion of conservation practices! Uncertainty about future events is not a reason for scrapping marginal user cost analysis<sup>5</sup> in determining the optimum rate of extraction that maximizes expected welfare. Although this method is subject to human fallibility in predicting the course of future events (as is any method of conservation), user cost analysis suggests the correct approach for husbanding resources—a claim that cannot be made for other prorationing schemes.

Hartshorn's discussion of royalty payments also suffers from a poor analytical treatment. Despite the fact that the author recognizes the "economic

---

variable cost ratio cannot be taken as *prima facie* evidence of economics of scale and (2) the oil industry is actually one of increasing costs. See M. Adelman, "The World Oil Outlook: An Academic View," forthcoming paper to be published in 1964 in *Resources and Economic Development* under the auspices of Resources for the Future.

<sup>4</sup>For a much shorter and more cogent analysis of oil prices, see M. Adelman, "Oil Prices, 1963-1975" to be published in the *Revue de l'Institut Français du Pétrole*.

<sup>5</sup>See P. Davidson, "Public Policy Problems of the Domestic Crude Oil Industry," *Am. Econ. Rev.*, March 1963, 53, 91-98.

rent" nature of royalties, he advocates a flat barrel royalty payment, and hopes that the companies and host governments can work out a new agreement which shifts the incidence of the royalty payments to the general taxpayers of the home nations of the oil firms (pp. 321-22). Hartshorn does not even realize that such a royalty agreement may be inequitable to the home taxpayers, and, even more importantly, it results in an inefficient allocation of resources. Royalties which are paid on either a per barrel or a percentage of gross revenue basis tend to convert a supplementary cost (a rent) into a prime cost, and therefore it will affect the short-run supply function.<sup>6</sup> In a world of perfect certainty and competition, of course, the income distribution between producers and host nations would not be any different than if royalties were paid as fixed sum. With uncertainty, however, it is possible for host nations to receive an amount which differs from the *ex post* rents involved. Since the concession contract may last for many years, the short-run marginal royalty costs can have a substantial and long-time effect on the rate of production. Consequently, proper analytical treatment would suggest that royalties should be paid on a unit of time basis rather than on a production basis. This would make royalties a supplementary cost—which, since royalties are economic rents, is as it should be.

In summary, it can be stated that although Hartshorn has addressed himself to an area that urgently needs objective study in order to formulate an "efficient" public policy, he has done little to promote an understanding of the problem. In fact, the nonexpert reader in this field is likely to be misinformed by this work.

PAUL DAVIDSON

*University of Pennsylvania*

\* *Ibid.*, pp. 90-91. Hartshorn provides an example of the impact of payments based on production to host nations on production rates when he notes that production from Venezuela declined significantly when payments to the host government were increased (pp. 273-74).

*Middle East Oil Crises and Western Europe's Energy Supplies.* By HAROLD LUBELL. Baltimore: The Johns Hopkins Press, 1963. Pp. xv, 233. \$8.75.

Considering the economic and political implications of Western Europe's growing dependence on imported fuels for the Free World, it is not surprising to see that the above-mentioned book is part of a research program carried out by The RAND Corporation for the United States Air Force. The author of this study, Harold Lubell, has previously examined for The RAND Corporation the Soviet oil offensive [1] and is an expert in oil economics with a great grasp of the political factors which always seem inseparably tied with questions concerning oil all over the world.

The pivotal issue of the present study is Western Europe's predominant dependence on oil from the Middle East and economic consequences if supplies from this source are, for one reason or the other, denied to her. The crux of the problem lies, as the author observes, in a pronounced lack of concern in Western Europe about a possible threat to its vital overseas oil supplies. The reason usually advanced for this attitude is a belief that the oil-

producing countries, particularly those in the Middle East, cannot be expected to act in unison (a) for a host of mutual political differences; and (b) because the present and territorially diversified great surplus of oil would make an attempt to cut Europe from its Middle East supplies economically ineffective.

Lubell, who doubts the soundness of such opinions, therefore, starts his inquiry with a preliminary examination of political and economic issues which led to the Iranian oil stoppage from 1951 to 1954 and the Suez crisis of 1956. The conclusion he draws from these precedents, that a repetition of similar stoppages in the Middle East oil shipments cannot be excluded from consideration is, of course, not startling. His position also finds support in the present tension generated by growing demands pressed by the steadily enlarging Organization of Petroleum Exporting Countries (OPEC).

It should be observed, however, that the scope of Lubell's inquiry is restricted, first, to the economic impact of a partial or complete interruption of oil deliveries from the Middle East only. Second, it is presumed that an ultimate alternative source of oil for Western Europe will be the Western Hemisphere, which practically means the United States and Venezuela. Thus, the study excludes any examination of the role which Soviet oil may play during an effective stoppage of Middle East shipments; neither does it consider the weight which potential availability of the Soviet crude may carry in a decision-making process of other oil producing countries. Of some significance for the author's conclusions is his further assumption that African oil will not materially diminish European dependence on the Middle East since, as he surmises, such oil will replace crude from the Western Hemisphere rather than from the Middle East. This in brief represents the framework of reference for Lubell's analysis which is executed at great depth and supported by an impressive array of quantitative data.

The analysis is divided into three parts. The first deals with several possible patterns of crises in the Middle East and their varying effect on the area oil output, oil transportation routes, tanker requirements, and freight rates. The second part is a detailed scrutiny of technical and economic problems that the oil industry in the Western Hemisphere would face under conditions explored in the first part of the book. In turn, the anticipated repercussions of an emergency expansion of oil output in Western Hemisphere on the oil-delivered prices in Western Europe are analyzed. In the third part, the new fuel supply situation is examined from the point of Western Europe's interest in staving off, or at least mitigating, damaging effects on her economy of a possible breakdown in the Middle East oil shipments.

In main, only two fundamental alternatives seem to be open to Western Europe. One is the attainment of the highest possible degree of autarchy in indigenous energy production and this essentially means maintenance of excessive coal-producing capacity. The other alternative is to rely predominantly on Western Hemisphere fuels and supplement them with an appropriate stockpiling policy. It would also require maintenance of excess oil capacity in Western Hemisphere and surplus tankers under Western control. If the comparative economic cost only is considered, the second alternative seems to be the most advantageous for Europe.

Once the author's premises are accepted, no serious objections can be raised to his conclusions. Of course, a few doubts may be expressed with respect to the validity of some of the study limitations and assumptions. For one, availability of African oil *does* affect the significance of the Middle East for Europe. This is clear from the fact that the former's share in total oil supplies of the Economic Community rose from 7 per cent in 1960 to (estimated) 19 per cent in 1963, whereas the relative share of the latter area declined from 71 to (estimated) 62 per cent in the same period [2]. The elimination of any analysis of the impact which availability of Soviet oil may have on a potential outbreak of another Middle East crisis may also be questioned. It is not hard to imagine, though, that in spite of all appearances the fact that the Soviet pipelines now extend to the very confines of Western Europe may be one of the main reasons for European complacency about security of its future oil supplies.

Nevertheless, these remarks hardly diminish the great contribution Lubell makes to our knowledge of oil economics. Four appendices, of which the linear programming of the economic cost for Europe of restricted availability of oil, written by K. J. Arrow, merits special attention, add to the value of this scholarly and objective study.

#### Labor Economics

*Government and Agriculture: Public Policy in a Democratic Society*. By DALE E. HATHAWAY. New York: Macmillan Publishing Co., 1963. Pp. viii, 412; \$8.95.

This book is a combined economic and political analysis of agricultural policy. While it is not entirely unique in combining these two elements of policy, it does put more weight on economics than previous books (e.g., Wesley McCune, *Who's Behind Our Farm Policy*, New York, 1957) which emphasized the political aspects and more weight on politics than other books (e.g., Harold Halcrow, *Agricultural Policy of the United States*, Englewood Cliffs, N.J., 1953, and Earl O. Heady, *Agricultural Policy Under Economic Development*, Ames, 1962) which have emphasized the economic aspects of agricultural policy. The contents of the book are weighted more heavily to the political foundation of policy than to fundamental economic analysis of farm programs and policy formulation.

The book is largely a literary analysis of farm policy and can be under-

stood readily by the undergraduate and noneconomist. Hence, it should have a broad impact on increasing public understanding of the origin of farm problems, alternatives in their solution, values and beliefs underlying policy positions of various groups, and the political basis of conflict in farm policy. It is well written for these purposes, using even geometry very sparingly in the economic analysis.

Professor Hathaway initiates his analysis with a discussion of the beliefs and values underlying U.S. farm policy and returns to this foundation throughout the book. In this respect, paralleling other farm policy discussions of the last few years, he emphasizes political and social stability, economic stability, economic organization, economic growth, equality of opportunity, and sharing of U.S. abundance abroad. Chapter 2 includes a detailed numerical description and a detailed interpretation of economic conditions in American agriculture. Chapter 3 includes a short discussion of such policy goals as family farms, parity, equal bargaining power, food for peace, and freedom. Part II of the book includes an empirical presentation of the economic reasons for farm problems and the author's interpretation of the relevant variables and forces affecting the income and structure of farming. Part III deals with the processes of policy formulation, the role of the various participants: Congress, the executive, and farm organizations. Part IV deals with alternative policies or proposed policies and their economic and political possibilities in solving the major farm problems of disequilibrium, instability, and poverty. Policies discussed in detail include free market prices, demand expansion programs, output control, direct compensation and taxation and programs outside of agriculture (e.g., full employment, labor migration, etc.).

The author assumes or concludes that the free market will neither solve the problem of disequilibrium in agriculture nor be acceptable to farmers and other groups closely related to agriculture. He makes a highly complete and clear interpretation of certain economic facets of programs that have been used or proposed as substitutes for a market economy. He does not, however, detail a systematic set of policy elements to solve the major economic problems of agriculture. His interlacing of the complexities in economics and political structure goes far in explaining realistically why "the farm policy mess" exists.

To a slight extent, the book is a debate with W. W. Cochrane (*Farm Prices, Myth and Reality*, St. Paul, 1958) on the reasons for the farm problem and the alternatives in its solution. The author rejects the static competitive theory of the firm as a basis for understanding farm policy problems. Yet where he dips deepest into economic tools, he resorts (e.g., pp. 110-25 and 279-80) to this very set of concepts.

Hathaway has provided a "down to earth" analysis of farm policy problems and formulation. It is a treatise which will broaden the knowledge of a wide group of possible readers.

"... a detailed examination of scientific research proposals submitted during a two-year period by two large universities for consideration by Federal and other sponsors. . . . Approximately two-thirds of the more than 2,000 proposals eventually received support, the study shows. . . . Proposals for renewal of research grants or contracts were 95 percent successful, while proposals for support of new work were 60 percent successful. Nearly 85 percent of the proposals submitted to more than one sponsor were rejected by all sponsors. . . . Proposals requesting between \$10,000 and \$25,000 were more numerous than those in the next most frequent range of \$25,000 to \$50,000."

# NOTES

## ECONOMICS LIBRARY SELECTIONS

The Department of Economics and the Center for Regional Economic Studies of the University of Pittsburgh announce that they are resuming publication of the Economics Library Selections List effective during the winter of 1963-64. This series, originally published at the Johns Hopkins University in March, 1954, was discontinued in the fall of 1962.

Series I of the Economics Library Selections List is a quarterly publication providing *annotations* of all books presently being published in English. It also contains annotations of many books published in German, French, and Spanish. In addition, a recommendation regarding the minimum size library (based on annual appropriation for economics books purchases) is made. Each book is also "evaluated" in terms of the type of teaching or research library for which it might be suitable. The books are arranged according to the principal subdisciplines of economics.

It has become necessary to sell these annotated bibliographies. The price to individuals (not associated with a subscriber library) is \$5.00 per year. The price to libraries is \$10.00. However, any library subscribing to the series is entitled to enter supplementary subscriptions for faculty at that institution at the rate of \$2.00 per subscription and for its students at the rate of \$1.00 per subscription. It will, of course, be necessary to identify the faculty and student subscribers.

The distribution of this publication is to be handled by the publishing firm of Gordon and Breach. Communications regarding subscriptions should be sent directly to them at 150 Fifth Avenue, New York 11, New York. Queries regarding publication policy and all editorial matters should be addressed to the Economics Library Selection Lists, 211 S. Dithridge Street, Pittsburgh 13, Pennsylvania.

## JOURNALS

*The National Banking Review* is a new quarterly journal. It is published by the Office of the Comptroller of the Currency and includes articles, both practical and theoretical, from the points of view of the banker, the economist, the lawyer, and the public administrator. Current banking and economic developments and current changes in law and regulation will be presented in each issue. Address inquiries to Editor, *The National Banking Review*, Office of the Comptroller of the Currency, U.S. Treasury Department, Washington 25, D.C.

---

The Library of International Relations is publishing, quarterly, *International Information Service*, an annotated listing of materials in the fields of economics, political science, geography, and others. The coverage is approximately 1000 current periodicals published in all parts of the world. Inquiries should be sent to 660 North Wabash Avenue, Chicago 11, Illinois.

---

A new journal, *The German Economic Review*, appeared recently. This is an English language quarterly on German economic research and current developments. The initial issue contained articles, book reviews, a selected bibliography, reports, and news. Inquiries may be addressed to the Editorial Office, D. Held, Authenriethstrasse 21, 74 Tübingen, Germany.

---

The Institute of Asian Economic Affairs is publishing in English a new journal, *The Developing Economies*. Inquiries should be sent to the Editor, 42 Honmura-chō, Ichigaya, Shinjuku-ku, Tokyo, Japan.

---

*The Journal of Air Law and Commerce* is now being published at the School of Law of Southern Methodist University. Authors are invited to submit manuscripts dealing with questions of the regulations of the industry, domestic or international, economic or financial problems of the airlines, or such other topics as may be included within the subject matter suggested by the *Journal's* title. Manuscripts should be submitted to the editor, Professor Richard J. Barber, School of Law, Southern Methodist University, Dallas, Texas, 75222.

#### ANNOUNCEMENTS

The American Council of Learned Societies invites interested scholars to call to its attention the titles of books in the humanities and social sciences, written in languages not widely known in this country, that deserve to be published in translation for the use of American scholars. The ACLS has initiated a program devoted to making such works available by sponsoring their translation into English; it will not itself publish them, but it will arrange for their publication.

Works proposed for translation should be major works of scholarship that are not available in any of the four languages—French, German, Spanish, Italian—that American scholars may be assumed to read without great difficulty. Suggestions should be addressed to the Scholarly Translations Program, American Council of Learned Societies, 345 East 46th Street, New York, 10017. Each nomination should include an analytical précis of the book in either English or French, together with the name and address of at least one scholarly authority who is competent to evaluate the work's importance to American scholars.

For the 17th consecutive year, the Survey Research Center of the University of Michigan will hold a Summer Institute in Survey Research Techniques. The Institute is designed to meet some of the educational and training needs of men and women engaged in business and governmental research and other statistical work, and graduate students and university instructors interested in quantitative research in the social sciences.

The 1964 Institute will be presented in two four-week sessions, the first from June 22 to July 18 and the second from July 20 to August 15. These two sessions may be taken independently or successively. For further information please write to the Survey Research Center, University of Michigan, P.O. Box 1248, Ann Arbor, Michigan, 48106.

#### Deaths

Lee Bidgood, Tuscaloosa, Alabama, May 17, 1963.

Kenneth H. Campbell, Washington, D.C., March 24, 1963.

John Maurice Clark, professor emeritus, Columbia University, June 27, 1963.

John Culliton, professor, department of economics and political science, McGill University, October 31, 1963.

Editha Hadcock, DePauw University, December 9, 1963.

Abram Harris, professor of economics, University of Chicago, November 16, 1963.

H. Gordon Hayes, New Orleans, Louisiana, May 4, 1963.

H. P. B. Jenkins, Lawrence, Kansas, formerly at the University of Arkansas, January 26, 1963.

Vernon D. Jolley, professor, department of business and economics, Marshall University, November 14, 1963.

Otto von Mering, Lucerne, Switzerland, June 17, 1963.

Mildred Benedict Northrup, chairman, department of economics, Bryn Mawr College, October 18, 1963.

Dennis Robertson, Trinity College, Cambridge, England, April 21, 1963.

Richard C. Wilcock, Institute of Labor and Industrial Relations, University of Illinois, December 8, 1963.

*Retirements*

Arthur R. Burns, Columbia University, June 1963.

Howard L. Jones, professor of statistics, Graduate School of Business, University of Chicago, October 1963.

Samuel S. Stratton, president, Middlebury College, September 1963.

V. Judson Wyckoff, DePauw University, June 1964.

*Visiting Foreign Scholars*

Oje Aboyade, The University College, Ibadan, Nigeria: visiting assistant professor of economics, University of Michigan, academic year 1963-64.

Edwin O. Alcántara-Pons, Universidad Raval Landívar and Consejo Nacional de Planificación, Guatemala: visiting lecturer, department of economics, University of Texas.

Paul Braesz, University of Cologne, Germany: visiting professor of economics, Pennsylvania State University, spring 1964.

Sukhamoy Chakravarty, Delhi University: visiting associate professor of economics, Massachusetts Institute of Technology, academic year 1963-64.

Ragnar Frisch, University of Oslo: visiting professor of economics, University of Pittsburgh, winter trimester 1964.

George Morton, London School of Economics: visiting professor of economics, University of Wisconsin-Milwaukee, academic year 1964-65.

Labhras O'Nuallain, University College, Galway, Ireland: visiting lecturer in international business, College of Business Administration, Boston University, 1963-64.

M. M. Poston, Cambridge University, England: visiting professor of economics and history, Institute of Industrial Relations, University of California, Berkeley, spring semester 1964.

Jan Sandee, Central Planning Bureau, The Hague, Netherlands: visiting professor of economics, Massachusetts Institute of Technology, academic year 1963-64.

*Promotions*

Redmond J. Allman: professor, economics department, Bentley College.

Albert K. Ando: associate professor of economics, Massachusetts Institute of Technology.

George W. Berry: associate professor of finance, Texas Technological College.

Dale L. Cramer: professor, department of economics, University of Alabama.

James A. Crutchfield: professor of economics, University of Washington

Edward Y. George: associate professor, Bentley College.

Manuel Gottlieb: professor of economics, University of Wisconsin-Milwaukee.

William D. Heier: assistant professor, College of Business Administration, University of South Florida.

Lester S. Levy: professor of economics, Texas Technological College.

Harry A. Marmion: associate professor of economics, U.S. Coast Guard Academy.

Alvin L. Marty: associate professor, department of economics, The City College of New York.

Richard E. Neel: associate professor, College of Business Administration, University of South Florida.

Phillip Nelson: associate professor, department of economics, New School for Social Research.

William H. Peterson: professor of economics, Graduate School of Business Administration, New York University

John H. Reese: associate professor of finance, Texas Technological College.

- Philip Ross: assistant professor, Graduate School of Business, University of Pittsburgh.  
 Franklin R. Shupp: associate professor, University of Illinois.  
 Robert M. Stern: associate professor of economics, University of Michigan.  
 Charles M. Sullivan: professor, economics department, Bentley College.  
 Lynn Turgeon: associate professor of economics, Hofstra University.  
 James Vaughan: assistant professor, Graduate School of Business, University of Pittsburgh.  
 St. Stanley Wasowski: associate professor, department of economics, Georgetown University.  
 June Zaccone: assistant professor of economics, Hofstra University.

### *Administrative Appointments*

David A. Baerncopf: acting head, department of accounting and business statistics and associate professor of business statistics, School of Business Administration, University of Oregon.

Dwight S. Brothers: acting chairman, department of economics, Rice University, 1963-64.

Frank C. Child: chairman, department of economics, University of California, Davis.

Gregory C. Chow: head, Economics Research Group, IBM Research Center.

Darwin W. Daicoff: director and chief economist, Office of Economic Analysis, State of Kansas.

Thomas W. Douglas: director, Industrial Relations and Personnel Management Program, The American University.

William C. Frederick: acting dean, Graduate School of Business, University of Pittsburgh.

Charles E. Johnson: dean, College of Liberal Arts and professor of accounting, University of Oregon.

L. C. Jurgensen: chairman of the accounting program, College of Business Administration, University of South Florida.

James W. Kelley: acting dean, College of Business Administration, Boston University.

Walter H. Klein: assistant dean, College of Commerce and Finance, Villanova University.

Robert E. Miller: chairman, department of economics and business, University of Tampa.

David L. Mosconi: chairman, department of finance, College of Business Administration, University of Denver.

James Owens: assistant to the dean, in charge of MBA program, School of Business Administration, The American University.

Stuart A. Rich: director, Forest Industries Management Center and associate professor of industrial marketing, School of Business Administration, University of Oregon.

Marshall A. Robinson, University of Pittsburgh: director, Program in Economic Development and Administration, Ford Foundation, New York.

Daniel D. Roman: director, Production and Research and Development Management Programs, The American University.

Warren L. Smith: chairman, department of economics, University of Michigan.

Wolfgang F. Stolper: director, Center for Research on Economic Development, University of Michigan.

William S. Vickrey: chairman, department of economics, Columbia University, July 1964.

Jacob Weissman: acting chairman, department of economics, Hofstra University.

### *Appointments*

- Warren E. Adams, University of Texas: program economist, USAID, New Delhi, India.  
 Andrzej Brzeski, Wayne State University: acting assistant professor of economics, University of California, Davis.

Robert H. Burton: assistant professor, College of Business Administration, University of South Florida.

Ivan T. Call, Valley National Bank: assistant professor of business administration, Brigham Young University.

William Capatch, University of Pittsburgh: Kent State University.

Simone Clemhout: lecturer, department of economics, The City College of New York.

Charles Cole, University of Southern California: assistant professor of economics, Occidental College.

W. D. Comer: assistant professor of finance, Texas Technological College.

Albert Conley: associate professor of economics, School of Business, East Carolina College.

Guenter Conradus, University of Washington: instructor in economics, Occidental College.

George Constantacopoulos: assistant professor of economics, Rutgers—The State University.

Charles Cooper, University of Pittsburgh: Indiana State College.

W. K. Cunningham: assistant professor, College of Business Administration, University of South Florida.

T. M. Dickerson: lecturer, College of Business Administration, University of South Florida.

Richard E. Dutton: assistant professor, College of Business Administration, University of South Florida.

James O. Eaton: visiting professor of accounting, School of Business Administration, University of Oregon.

Robert W. Fogel, University of Rochester: associate professor, department of economics, University of Chicago, October 1964.

Padraic P. Frucht, U.S. Dept. of Commerce: associate professor, department of economics, College of Business Administration, University of Florida.

David Funk: instructor, department of economics, Wellesley College.

John J. Griffin, Jr., Federal Reserve Bank of New York: instructor, department of economics, Graduate School of Business Administration, New York University.

Delmar Hartley: assistant professor of finance, Texas Technological College.

John Howard, University of Pittsburgh: Columbia University.

Ralph James: associate professor of economics, University of California, Davis.

Richard A. Jenner: assistant professor of economics, Rice University.

Alice Hanson Jones: visiting instructor, department of economics, Washington University, academic year 1963-64.

Hiromitsu Kaneda: lecturer, department of economics, University of California, Davis.

Richard F. Kosobud: lecturer in economics, University of Michigan.

Edward Kuriger: instructor, department of economics and business administration, Geneva College.

Richard A. Ladd: assistant professor of economics, U.S. Coast Guard Academy.

Mordechai Lando: instructor in economics, Hofstra University.

Richard E. Low: assistant professor of economics, Pennsylvania State University.

Anthony Luchek, University of Wisconsin-Milwaukee: Labor Affairs Adviser, USAID, Indonesia.

Paul W. MacAvoy: assistant professor of economics, Massachusetts Institute of Technology.

J. F. McMullan: assistant professor, College of Business Administration, University of South Florida.

Thomas Mayer: professor of economics, University of California, Davis.

W. G. Modrow: assistant professor, College of Business Administration, University of South Florida.

R. Joseph Monsen, Brigham Young University: associate professor, department of general business, College of Business Administration, University of Washington.

Roy E. Moor, staff, Joint Economic Committee: administrative assistant to Senator William Proxmire.

Oscar Moore: associate professor of economics, School of Business, East Carolina College.

Alan Page Murray, Office of Tax Analysis, U.S. Treasury Department: staff, Joint Economic Committee.

Hong-Lan Oei, University of Texas: junior economist with U.N., ECAFE, Bangkok.

Roy Ott, Jr.: associate professor, department of finance, University of Alabama.

Robert A. Parsons: assistant professor, economics department, Bentley College.

Louis Pondy: instructor in business administration, Graduate School of Business, University of Pittsburgh.

Martin L. Primack: associate professor of economics, Bentley College.

Otto R. Reischer: economic adviser, Investment Advisory Center, Government of Pakistan, Karachi.

T. Donald Rucker, Michigan Medical Service: research economist, National Association of Blue Shield Plans.

Trevor Sainsbury: assistant professor, Graduate School of Business, University of Pittsburgh.

Lewis M. Schneider: assistant professor of business administration, Harvard University.

Richard Thomas Selden, Columbia University: professor of economics, Cornell University.

W. A. Shannon, Jr.: instructor, College of Business Administration, University of South Florida.

T. Y. Shen, Wayne State University: associate professor of economics, University of California, Davis.

David Singer: instructor in economics, Hofstra University.

Herbert Stein: State Supreme Court, Harrisburg, Pennsylvania.

Lewis M. Stewart: instructor in economics, Texas Technological College.

Vladimir Stoikov, Wesleyan University: associate professor, Queens College, City University of New York.

John J. Surmeier, RAND Corporation: operations analyst, Research Analysis Corporation.

Edwin Terry: assistant professor, department of economics, Washington University.

Arthur L. Thomas: assistant professor of accounting, University of Oregon.

Robert P. Thomas, Northwestern University: acting assistant professor, University of Washington.

Richard H. Tilly: lecturer in economics, University of Michigan.

Gerhard Tintner: professor of economics and mathematics, University of Southern California.

Donald L. Thompson: assistant professor of marketing, University of Oregon.

Robert J. Trusk: economist, Near East and South Asia Section, Eximbank, Washington, D.C.

Sheila Tschinkel: assistant professor of economics, University of Alaska.

Hirofumi Uzawa, Stanford University: professor of economics, University of Chicago, July 1964.

Ella May Webb: instructor, College of Business Administration, University of South Florida.

Byron White: associate professor of economics, School of Business, East Carolina College.

*Leaves for Special Appointments*

W. H. Locke Anderson, University of Michigan: staff, Council of Economic Advisers, academic year 1963-64.

John H. Auten, Rice University: economic consultant, U.S. Treasury Department, 1963-64.

Wesley Ballaine, University of Oregon: consultant, University of the Andes, Venezuela, May to July 1964.

Barbara Berman, Brandeis University: Brookings Institution, academic year 1964-65.

Arthur I. Bloomfield, University of Pennsylvania: visiting professor, Princeton University, fall term 1963-64.

John S. Chipman, University of Minnesota: visiting professor of economics, University of Rochester, first semester.

George Dalton, Northwestern University: International Labour Office, Geneva, 1964-65.

Laurence deRycke, Occidental College: consultant, University del Valle, Columbia, December 1963 to summer 1965.

Edward O. Edwards, Rice University: Ford Foundation in Kenya, 1963-64.

Milton Friedman, University of Chicago: visiting research professor, Columbia University.

Daniel R. Fusfeld, University of Michigan: director, Manpower, Development, and Training Activities Branch, Office of Program Planning, U.S. Office of Education, academic year 1963-64.

W. Lee Hansen, University of California, Los Angeles: staff, President's Council of Economic Advisers, 1964.

Harvey J. Levin, Hofstra University: Carnegie Fellow in Law and Economics, Harvard University.

Fritz Machlup, Princeton University: visiting professor, doctoral program in economics, City University of New York, 1963-64.

Sid Mittra, University of Detroit: Senior Economic Consultant, Simulmatics Corporation Project, Venezuela.

David H. Pollock, Chief, United Nations ECLA Washington Office: Special Assistant to the Secretary-General of the United Nations Conference on Trade and Development, through mid-1964, in Geneva, Switzerland.

Melvin W. Reder, Stanford University: visiting professor of economics, University of California, Berkeley, spring semester, 1964.

Stefan H. Robock, Indiana University: United Nations Special Adviser on Economic Planning, Bolivia, 3 months 1963.

Wilson E. Schmidt, George Washington University: visiting professor of economics, Bologna Center, Johns Hopkins University, 1963-64.

Stephen Spiegelglas, Boston University: AID mission to Turkey.

Lynn Turgeon, Hofstra University: Institute of Economics, Academy of Sciences, USSR on exchange, sponsored by the American Council of Learned Societies, fall 1963.

Donald A. Watson, University of Oregon: consultant, University of the Andes, Venezuela, January to March 1964.

Robert E. Weintraub, The City College of New York: senior economist, House of Representatives Banking and Currency Committee, spring 1964.

J. N. Wolfe, University of California, Santa Barbara: Brookings Research Professor, 1963-64, attached to National Economic Development Office, London.

James S. Youtsler, Skidmore College: visiting professor, American University of Beirut, 1963-64.

*Resignations*

Marto A. Ballesteros, University of Washington.

Francis M. Bator, Massachusetts Institute of Technology.

James F. Jackson, Jr., University of South Florida.

Robert B. McNee, The City College of New York.

*Correction*

The issue of December, 1963 carried an item, under appointments, about David McCord Wright that was misleading. It should have stated that his permanent position is with the University of Georgia; that he resigned as trustee of the Foundation of Economic Education; and that he was appointed economic consultant to the Federal Reserve Bank of Atlanta.

## IMPORTANT NOTICE TO MEMBERS

The Executive Committee of the American Economic Association has authorized our participation with ten other national professional associations in the National Science Foundation's 1964 Register of Scientific and Technical Personnel. In connection with this project, you will be receiving a questionnaire sometime during March. Because the information provided by your answers will enable us to make a detailed analysis of the structure of the economics profession, members are urged to cooperate by filling out and returning the questionnaire at their earliest convenience.

VOLUME LIV

JUNE 1964 NUMBER FOUR, PART I

THE AMERICAN ECONOMIC ASSOCIATION, 1904-29

By A. W. COATS\*

## *Prologue*

At its birth in 1885 the American Economic Association was a healthy infant whose lusty cries for attention and nourishment soon attracted enough interest and support to ensure that it would enjoy a vigorous and effective life. Yet even the most auspicious beginnings could not entirely counteract the effects of heredity. The offspring of mixed parentage—European scholarship and Yankee social reform—the Association revealed even before its seventh year those schizoid tendencies which were to continue in evidence throughout its adolescence and early adulthood. The inherited tensions resulting from the conflicting attractions of pure science and public service were, admittedly, reinforced by environmental influences. But even when the environment became more favorable, when the internal divisions among its members had faded into the mists of memory, and when the foundations of a long and fruitful career had been securely laid, there still remained doubts—not only about the most effective methods of achieving the Association's purposes, but also about the very nature of those purposes.

## *I. Introduction: Scholarship or Survival?*

It is often difficult to discern clearly demarcated turning-points in the life of an individual or the development of an organization, and there are no compelling reasons why the second instalment of the history of the American Economic Association should begin in 1904 [6] [8]. However, that year witnessed the formal burying of a hatchet and the inauguration of what the Secretary called an "era of good feelings" [1, F. A. Fetter to E. R. A. Seligman, Apr 4 1904] for, after delicate and protracted negotiations, it was decided that the next annual meet-

\*The author is reader in economic and social history at the University of York, England. This article is a sequel to one published earlier in this *Review* [6], and the author wishes to thank the Secretary of the Association, Harold F. Williamson, and his Research Assistant, Richard Buth, for their help in finding and photocopying source materials.

ing should be held at the University of Chicago, whereupon J. L. Laughlin, Head of the Department of Economics at Chicago and the only prominent survivor of the "old school" opposition to the American Economic Association, graciously accepted the inevitable and at last became a member. This happy event<sup>1</sup> did not, of course, mark the complete disappearance of "the petty and ridiculous politics that seem to be inseparable from the conduct of all American associations."<sup>2</sup> The wide variety of interests and the geographical dispersion of the Association's membership were themselves sufficient to ensure the persistence of disagreements about its policy—as, for example, in the perennial problem of choosing a suitable location for the annual meeting. Nevertheless, from the early years of this century, personal, doctrinal, and institutional rivalries played a subordinate role in the organization's history, and under its benevolent and enlightened leadership the unity of the American economists was assured.

In a sense, 1904 marks the end of the parochial phase of the A.E.A.'s history, and in subsequent years its officers were free to devote more of their time and energy to the task of establishing and enhancing its position on the national stage. This does not mean that their trials and tribulations were over: for although the Association's position as the leading organization of American economists was rarely questioned, its precise character and purpose remained in doubt, and from time to time financial difficulties threatened its very existence. In this case, as so often occurs, ends and means were interdependent, and in times of crisis the future of the organization seemed to hang on the outcome of a struggle between scholarship and survival. This struggle was not solely or even mainly attributable to financial difficulties; nor was it an unusual experience for a scholarly organization in the United States, since it reflected the basic insecurity of the intellectual's position in American society. Nevertheless, the problem presented itself to the economists in an especially acute form because the scientific status of their discipline was open to question, and they were torn between the conflicting claims of scholarship and public service. Both as individuals and as an organized body, the American economists sought to enhance their public prestige and influence, especially

<sup>1</sup> "Laughlin's paper alone . . . was quite enough for the entire session, and I felt much sympathy with his exclamation at the close that he wished we had three hours to debate this subject. . . . Certainly the meeting in Chicago must be counted a very successful one from the point of view of attendance, spirit and interest" [1, Fetter to F. W. Taussig, Jan 6 1905].

<sup>2</sup> [1, F. H. Giddings to Fetter, May 3 1902]. This remark was made in the course of the interminable debate over the question of an A.E.A. journal, a topic which was first raised in the early 1890's and finally settled with the publication of the *American Economic Review* in 1911. An account of this debate must be postponed until a subsequent occasion.

with the business community, without at the same time jeopardizing their reputation as detached, impartial scientists. To the individual economist the problem of deciding how to divide his time and energy between the groves of academe and the market place was a subjective one, to be resolved by a personal decision which, even if conscious, was seldom irrevocable; and for many economists the outcome must have been largely determined by the chance availability of employment opportunities. To the officers of the American Economic Association, on the other hand, this problem necessarily assumed a more overt, institutional form, and the solutions adopted are revealed in the membership campaigns, in the effort to avoid public policy commitments, in the conduct of the Association's annual meetings, and in the form and content of its publications. In view of the wider issues concerning the position of the professional economist in American society, an examination of these mundane affairs possesses an interest which transcends the parochial or the antiquarian. If, for example, we find that by the end of the 1920's the American Economic Association had solved its internal, organizational problems and had come to terms with its environment, we may thereby obtain some indication of the progress (or perhaps the corruption) of American scholarship.<sup>3</sup> If, however, these problems were still unsolved, we are automatically provided with a number of pertinent questions about the subsequent development of American economic thought.

## II. *The Size and Character of Membership*

If one may judge an organization by its membership, the American Economic Association has never been a purely scholarly and scientific body, and in this respect its policy has consistently adhered to the wishes of the young rebels who founded it in the 1880's partly in protest against the domination of American economic thought by what they conceived to be an exclusively orthodox "school" [6] [8] [7]. In its initial, reformist phase, when the first Secretary, Richard T. Ely, was largely responsible for these matters, determined efforts were made to enlist the support of a wide variety of nonacademic persons, and the early membership lists included a high proportion of clergymen (some of whom were also college professors). Yet even at that stage there were some members who wondered whether the desire for comprehensiveness and catholicity were being pushed too far, and this doubt recurred from time to time in later years.

During the late 1890's, a conscious effort was made to arouse the

<sup>3</sup> The question "Are the Economists a Bunch of Kept Cats?" was (not too seriously) discussed at the 1963 meeting of the Mid-Western Economic Association at St. Louis. For comments on the problem of professional ethics in the 1920's, see [9, pp. 208-11].

support of business and professional men [6, p. 571], and the first systematic membership campaign was undertaken by Ely, almost single-handed, in 1900-1902, while he was President of the Association. The timing of this campaign was no coincidence, for Ely not only possessed the requisite combination of character, skill, and outlook; he was also seeking to demonstrate his indispensability to an organization which he regarded, with only partial justification, as his own offspring. It was, however, a coincidence that the second membership campaign, launched in 1909, was conducted by a man of similar qualities, Thomas Nixon Carver. Like Ely, Carver possessed dynamic energy, considerable administrative skill, a taste and a talent for popularization, and a firm belief that the Association should play an active part in disseminating "sound" economic ideas and shaping public policy. His attitude towards the A.E.A. was, of course, less possessive than Ely's; but neither man displayed any hesitation in impressing his own forceful personality on the organization.

Both of these campaigns were prompted by a desire to increase the Association's activities at a time when its membership revenue was expanding slowly. The finances were, it is true, much stronger in 1909 than they had been ten years earlier; but the need for revenue was even greater because of the decision to begin publishing the *American Economic Review*. When Carver was elected Secretary, at the 1908 annual meeting, a membership committee was also appointed; but although the ensuing campaign gathered momentum the prospects of eventual success seemed poor for, as Carver showed in a lucid economic analysis of the problem incorporated in his Secretary's report for 1911, a very large increase in membership would be needed to make a significant addition to the Association's income. The campaign expenses were so high that each new member added a net marginal income of only \$1.40, and the rate of growth of income was far too slow to cover the expected rise of expenditure [3, pp. 132-37]. However, this analysis attracted the attention of a New York lawyer, Albert de Roode, one of Carver's former Harvard students, and he and a group of his business colleagues offered to provide a special fund of \$1,000 for the campaign. As he explained in a letter to Carver:

Our interest in the work is because we understand that the Association wishes to extend its scope and influence among the non-academic members of the community—in other words, the propagation of sound economic doctrine among the unenlightened and the stimulation of discussion on economic subjects among those not professionally interested in it.<sup>4</sup>

<sup>4</sup> [1, de Roode to Carver, Apr 9 1912. Also de Roode to Carver, Mar 18 1912; Sep 24 1912; Carver to de Roode, Apr 13 1912]. De Roode's name was at first unknown even

Carver readily accepted these terms of reference because they were in complete harmony with his own conception of the Association's functions, and de Roode's plan involved no change in either the character or the direction of the campaign. The most active person on the membership committee was Roger W. Babson, a professional statistical forecaster who became Chairman of the Committee in 1912, and he too was anxious to strengthen the Association's links with the business community. As it transpired, despite a considerable expenditure of time and money, the last stage of the membership campaign yielded disappointing results for, as Carver pointed out, a condition of diminishing returns had been reached, and a high proportion of the nonacademic recruits retained their interest for only a year or so and were sometimes aggrieved when they were subsequently asked to pay up their outstanding dues!<sup>5</sup>

In the present context, the numerical and financial details of the membership campaign are less interesting than its implications for the character and functions of the American Economic Association. Some members favored the "open" membership plan because it was "democratic," and when a Council member attended the inaugural meeting of the British Economic Association (later the Royal Economic Society) in 1890, he reported with evident satisfaction that the British economists had followed the American example in rejecting all proposals designed to restrict membership [11, p. 166]. Others, however, objected to the policy of "going into the far-flung highways for more neophytes" [1, O. F. Boucke to Secretary, May 1 1925], and when one circular called upon members to solicit subscriptions from local organizations and suggested that they might "take out membership for some friend as a Christmas present,"<sup>6</sup> there were grounds for thinking that the limits of scholarly and scientific dignity had been

---

to members of the membership committee. [Cf., 1, R. Babson to Carver, Apr 16 1912; Carver to Babson, May 6 1912; Fetter to Carver, Apr 12 1912; Carver to Fetter, May 21 1912].

<sup>5</sup> [4, p. 202]. During the period 1909-13 a net increase in membership of 1483 was claimed, and by December, 1915 Carver's successor, A. A. Young, considered that a state of "normal equilibrium" had been reached [5, p. 221]. However, the annual secretary's reports give somewhat different total membership figures, e.g., 1900-774; 1902-1111 (during Ely's campaign); 1908-1030; 1909-1360; 1913-2513; 1915-2422. The totals were continually being "pruned" by removing the names of delinquents. For subsequent figures, see *infra*, note 47.

One nonacademic member who had asked by what authority the Secretary proposed to cut him off on the grounds of nonpayment of his subscription eventually enclosed a check in settlement "of all claims of every kind and description, scientific, commercial or otherwise" [1, H. Stewart to Secretary, Mar 8 1919].

<sup>6</sup> This is taken from an undated circular, probably drafted in November, 1911, which may not have been actually sent out to members.

exceeded. Some of those invited to join accepted the honor with alacrity, remarking that they had only held back because they had assumed that they lacked the necessary qualifications;<sup>7</sup> but occasionally those who refused took the opportunity of expressing their opinion of academic economists and current economic policy in no uncertain terms!<sup>8</sup> The *reductio ad absurdum* of this promiscuous membership policy was the businessman who, having accepted Babson's invitation to join, wrote to the Secretary asking him to outline "a course of study that would not be too heavy, and to which a business man could give attention day by day with the hope of a fair mastery of this subject"; and Carver seems to have accepted this pedagogical function as a normal part of his secretarial duties.<sup>9</sup>

Another corollary of the Association's purely pecuniary criterion of membership was its unwillingness to be held responsible for either the personal character or the views of its members. For example, when the Secretary of the New York Reform Club offered to extend its facilities to members of the American Economic Association, he was warned:

... there is no test for membership in the Association. . . . The payment

<sup>7</sup> In a letter reminiscent of the responses to Ely's appeals in the early days of the A.E.A., the Pastor of the Congregational Church at Northbridge Center (Mass.?) expressed his appreciation of the nomination for membership and hoped soon to be able to send the Treasurer the proper credentials so as to ensure his enrollment. "In view of present world conditions I believe it is important that leaders of the new World Order [sic] such as leading economists either in actual business life or associated with it should unite to study the problems involved" [1, W. W. Evans to Secretary, May 23 1921]. (*Plus ça change, plus c'est la même chose.*)

Another respondent was pleased that he was not considered too radical to be a member but asked to see the Constitution in order to reassure himself that the A.E.A. was not like such other organizations as the New Haven Railroad, the International Motor Co., etc. "in each of which the membership has been ignored by the management and finds itself without recourse" [1, H. F. Stimpson to Secretary, Oct 18 1913; Nov. 14 1913].

<sup>8</sup> One respondent sent a curt telegram stating "Make your publications worth the money" [1, E. A. MacClean, New York City, Feb 4 1914]. Another associated the work of the A.E.A. with "the attempts of half-educated writers to direct and lead public thought," which had helped to feed the "mad ambition and lust of power by the reckless demagogue who once brought this country during the most prosperous period of its existence to the verge of ruin" [1, J. H. Moore, San Francisco, May 9 1912]. (He was presumably referring to Theodore Roosevelt.) However, the correspondent who described the economists as equivalent to "intellectual prostitutes" apparently had not been invited to join the A.E.A. [1, S. O. Gordon to Secretary, Apr 5 1922].

<sup>9</sup> [1, E. C. Miller to Carver, Mar 18 1912; Carver to Miller, Mar 26 1912]. Roger W. Babson had invited Miller to join the Association.

Another insight into the character of the membership was provided by the correspondent who, when asked to renew his subscription, replied, "Our subscription has been made to you from year to year for the purpose of being helpful to you, and not with a view to our own improvement. We never asked for your literature, nor did we expect to receive any . . . if it has been received we have been so unfortunate as not to have perused it" [1, F. Beidler to Secretary, Jun 11 1914]. Nevertheless, he paid his bill in full!

of annual dues is in itself prima facie evidence of an interest in economic questions, but our membership includes people of very different political opinions and social walks of life. There is a remote danger that if membership offers the additional privileges of your library, some might join for that purpose.<sup>10</sup>

Similarly, when Richard T. Ely's Institute for Research in Land Economics and Public Utilities was attacked in 1926 as "a cunning propaganda institute in disguise,"<sup>11</sup> the Association's officers resisted the demand for an investigation, not only because Ely was a distinguished officer of the Association and the source of the complaint was prejudiced, but also because "such an investigation would be outside the functions of this organization."<sup>12</sup> A somewhat similar sentiment had been expressed earlier by the Secretary, Allyn A. Young, in 1915 when the American Association of University Professors was founded, and some prominent members of the A.E.A. were heartily relieved at the prospect that the difficult and inconclusive business of investigating complaints of violations of academic freedom would be taken over by another organization.<sup>13</sup>

Unlike the governing bodies of the Royal Economic Society and the Scottish Economic Society,<sup>14</sup> the Executive Committee of the

<sup>10</sup> [1, Fetter to M. R. Maltbie, Oct 29 1904]. Maltbie had assumed he could "take it that the fact that they are members of the A.E.A. is sufficient guarantee of their character, and that no improper advantage will be taken of the library privileges." Fetter was not so sure, for he recalled how people had unsuccessfully sought membership in the A.E.A. in order to obtain free sets of the Census volumes which had been offered to members.

<sup>11</sup> E. O. Jorgenson, a representative of the Manufacturers' and Merchants' Federal Tax League, protested that the Institute "has laid down its conclusions in advance of its investigations" and "has, before any of its facts have been gathered, condemned certain far-reaching measures which an increasing number of scholars believe to be beneficial to the people and approved certain other far-reaching measures which many scholars also believe to be detrimental to the people," thereby completely disregarding "the principles of fairness and impartiality." Moreover, the Institute's conclusions "harmonise exactly with the views of the corporations and special privilege groups which are financing it." Although the Institute's host institution, "Northwestern University, strange to say, has ignored our protests entirely," Jorgenson enclosed a copy of his book, *False Education in our Colleges and Universities*, and demanded "prompt and rigid investigation" by a committee of the A.E.A. [1, Jorgenson to E. W. Kemmerer (President of the A.E.A.), Jul 31 1926].

<sup>12</sup> [1, Kemmerer to Jorgenson, Dec 30 1926]. This letter was written after a meeting of the Executive Committee of the A.E.A. Cf. Young to F.C. Deibler (Secretary): "The request that the Association institute an investigation of the Institute for Land Economics will be turned down flatly, I hope. This is not only because it is not the business of the Association to make such investigations, but also because the proposal is an insult to Professor Ely and his associates. It comes from an irresponsible and prejudiced source" [1, Dec 11 1926].

<sup>13</sup> [1, H. C. Adams to Young, Apr 26 1915; Young to Adams, May 5 1915].

<sup>14</sup> According to the by-laws of the Royal Economic Society, "if any Fellow or Honorary Fellow shall so conduct himself that, in the opinion of the Council, it would not be for the credit and advantage of the Society that he should longer continue to be a Fellow or

A.E.A. had no power to request the resignation of any member whose conduct was held to be prejudicial to the interests of the organization; nor is there any evidence either that such power was sought or that the economists ever even contemplated the establishment of any procedure for dealing with cases of unprofessional conduct. In this matter, fear of destroying the "open" character of the Association was reinforced by an acute awareness of the virtual impossibility of obtaining agreement about the nature and tests of professional work in economics.

### III. *The Problem of Professional Identity and Standards*

Like many of its individual members, the American Economic Association had a foot in two distinct worlds, the world of learning and the world of business, and it has never been easy to serve two masters simultaneously. The "open" membership policy, the question of professional standards in economics, and the problem of deciding how far the Association should cater to the needs and interests of businessmen were all interrelated, and while Carver and Babson were proponents of an activist policy which emphasized the Association's links with and responsibilities to the business community,<sup>15</sup> Carver's successor, Allyn Young, who was Secretary from 1913 to 1920, adopted a quite different standpoint. Emphasizing the scholarly and scientific objects of the organization, Young admitted his "reluctance to try to extend our membership among business men except in so far as they thoroughly understand our work"; and to Davis R. Dewey, the managing editor of the *American Economic Review*, he confided:

---

Honorary Fellow thereof, the Council shall take the matter into consideration at a meeting convened for the purpose." The Council of the Scottish Society of Economists, in the early years of this century, could delete the name of any member "at their discretion, and thereupon such member shall forfeit all rights and interest in the Society without the right of appeal." Cf. *infra*, note 18.

In response to a specific enquiry as to "what may be regarded as the proper standards of practice in the line of business which you represent," Deibler replied, almost facetiously: "You should know that our middle name is 'Ethics,' but we have no particular code" [1, R. A. Clemen, Chicago, to Secretary, Nov 15 1929; Deibler to Clemen, Nov 19 1929].

<sup>15</sup> Although on one occasion Carver wrote that "the main purpose" of the A.E.A. was "to run the affairs of the country in an economical and progressive way," he was aware of the duality of interests. "I hope the Association will never forget that it exists primarily in the interests of scholarship. Nevertheless, I think we have another important function, namely to act as a leaven to the whole national lump, and to do what we can to spread the habit of sound economic thinking among the business and professional classes, who have so much to do with the determination of national policies. Just how to maintain a proper balance between the interests of pure scholarship and those of popularisation must always be a difficult problem" [1, Carver to J. E. Woodbridge, Jan 20 1912; Carver to Prof. B. H. Putnam, Mount Holyoke College, Jan 24 1912].

I believe that we can make a sounder and more effective appeal to business men by putting the matter squarely on that basis (i.e. that they feel it an honor to be associated with us rather than merely getting their money's worth) than by attempting to cater in the slightest degree to their special interests as contrasted with those of the professional economists [1, Feb 18 1915; cf. Young to E. A. Pratt, Nov 11 1915].

The crux of the problem, however, lay hidden in that portmanteau term "professional," and this definitional difficulty assumed concrete form as Young went on to criticize the *Review* for printing too many merely "practical" and "topical" leading articles.

Such considerations as those of timeliness and of practical interest should be made distinctly subordinate in the selection of leading articles. Of course we ought to have at least one timely article in each number, but I do not think it should be necessary to go beyond that. Let me say frankly that this seems to be the opinion of a very large majority of members of the Association whom I have heard talk about the *Review*. They are satisfied with it in every way except the leading articles, and these they feel have not in general a sufficiently professional quality. [*Ibid.*]

These remarks not only raised questions about the precise meaning of the terms "practical" and "timely," "scholarly" and "professional"; they also suggested that academic and nonacademic members of the Association possessed distinct and contrasting interests—a notion that was not confirmed by the discussion evoked by Young's comments. To deny "professional" caliber to practical and timely articles was, *ipso facto*, to condemn them, for it clearly implied that the *Review* was failing to maintain the standards appropriate to a scholarly and scientific organization. Yet Young himself, when pressed, found it difficult to define the term "professional" in a satisfactory way. In a subsequent letter to Dewey he explained:

By articles of a distinctly professional or technical nature I meant articles which were shaped with primary reference to the interests and needs of economists, whether dealing with theory or with other matters. I would not put a merely descriptive article, written without reference to its bearing on fundamental questions of principle, under this head [1, Apr 12 1915].

This sweeping reference to the "needs of economists" represented a serious oversimplification of the problem, as is shown by the responses of members of the editorial board of the *Review*. The most decisive repudiation of Young's views came from H. E. Mills, who protested that his use of the expression "professional quality" was too vague and conveyed "a certain impression of desire for other worldliness." Mills continued:

Economics in America suffered because it was so professional and apart from real life. That time has happily gone because economists have come to study in a scholarly and professional way topics that are timely and have practical interest. College and university teaching deals more and more with concrete subjects in a professional and scholarly way. . . . I do not think we should "cater" to business men members; but on the other hand to separate from them is unwise and the Review may render a great service by showing to the business man the scientific and professional methods of approaching and handling concrete, practical questions. . . . It must be remembered that a large proportion of the trained and able economists of the country are now working upon and primarily interested in matters of practical significance, and hence articles of such character are likely to predominate.<sup>16</sup>

The reactions of other members of the editorial board, while on the whole supporting Mills rather than Young, also reveal the impossibility of drawing any sharp line between the categories "professional and scholarly" on the one hand, and "practical and timely" on the other. Herbert Davenport, for example, endorsed Young's opinion that few businessmen read the *Review*—a view that is confirmed by other correspondence in the Association's files—and added that most businessmen "would find what we call practical articles about as unusable as the very distinctly theoretical ones." But while opposing a policy of "going out for" more theoretical articles, he nevertheless considered that "if good stuff of the theoretical emphasis offers, we might wisely adopt a working presumption in its favour." Henry B. Gardner and Clive Day contended that the so-called "practical" articles not only helped professors to keep up with current questions of the day but had also proved to be of great value in teaching; and for most of the respondents the crucial question was not "balance" but "quality." Frank Fetter, for example, himself an economic theorist, considered that one good theoretical article was worth several concrete and descriptive ones; but he believed that few good theoretical articles were available:

Economic theory should be the product of the ripest and maturest economists, but most of them are interested in specific practical issues. It is the young men, hardly fully fledged, working for their doctor's degrees or little past that point who offer the major part of the manuscripts in theory, is it not, to say nothing of the rank amateur businessman or engineer who has lately discovered that "the earth do move." [*Ibid.*]

There was no deliberate change of editorial policy as a result of this

<sup>16</sup> Mills' comments, together with those of J. E. Coulter, H. Davenport, C. Day, F. A. Fetter, and H. B. Gardner, are preserved in the A.E.A. files.

discussion. Some economists believed that there was a tacit division of the market between the *American Economic Review* and its long-established rival, the *Quarterly Journal of Economics*, and on the basis of this supposition there may have been some tendency for authors to submit their more theoretical articles to the Harvard journal. But whatever the grounds for this belief, criticism of the *Review* was endemic, for it was impossible to please all the members of its heterogenous and widely scattered audience. As late as 1928 Dewey (who continued to be managing editor until 1940) was still patiently explaining that:

The range of interest of our constituency is appalling; and it has been assumed that the *Review* must meet all of these varied interests. No single individual partakes of all the items on the menu of a large hotel. He selects only a few; but the hotel apparently thinks it necessary to provide this wide selection [1, Dewey to Deibler, Mar 30 1928].

From time to time dissatisfied members proposed changes in the policy or composition of the Association, and these proposals clearly reveal the variety of interests involved. It was sometimes suggested that a professional association of nonacademic economists should be formed in affiliation with the American Economic Association, and on one occasion this suggestion was made by a business economist who was on the point of returning to a full-time academic post.<sup>17</sup> In 1915, shortly after the discussion of the *Review's* policy, a similar proposal was advanced by Dr. A. M. Sakolski, who was employed in the valuation office of the Delaware and Hudson Company, Albany, New York. Sakolski wrote to Allyn Young complaining that Roger Babson was taking unfair advantage of his connection with the Association, and suggesting "Isn't it time that a genuine scientias society of American economists should be formed, separate though not in opposition to the American Economic Society [sic]?" [1, n.d. (probably May 1915)]. Subsequently he elaborated his proposal which, he said, had been initiated by Dana Durand, Head of the Bureau of the Census, and his letter reveals the underlying motives:

The membership of a scientific society could be limited to members of the AEA having several years standing in the organization and also possessing the training, the qualifications and the activities of scientific economists. This arrangement would create an alliance without a definite

<sup>17</sup> [1, G. J. Eberle to J. H. Hollander, Jun 6 1921; Eberle to Westerfield, Dec 21 1921]. On Dec 15 1921 the Secretary dispatched a circular to members of the Executive Committee which referred to Eberle's proposal that the Association should establish "certain minimum qualifications for persons who call themselves professional economists" with the aim of protecting "the science and the professors, and to assure clients and prospective clients a certain standard of services." No action was taken.

corporate relationship. . . . Perhaps I feel more keenly about the matter than you, because I lack an academic connection and have no standing in a recognized profession. In spite of my official title, I am, after all, nothing but a clerk and cannot well claim the respect that is given lawyers, engineers and physicians in their duties. Only recently the American Society of Civil Engineers raised the qualifications for membership to their organization. If this policy were followed by the "scientific" group of the AEA it would, in my opinion, shut out the pseudo economists, statisticians, "industrial engineers," efficiency experts, etc. etc. who advertize their membership in the AEA as recognition of their scientific standing. Certainly teachers among economists, and especially those training men to follow this line of work, ought to favor the formation of a strictly professional society [1, Sep 23 1915].

While Sakolski's letter discloses some of the difficulties encountered by the would-be scientific economist in business, Young's sympathetic replies reveal the dilemma of his academic counterpart:

I do feel that the Economic Association has gone too far in catering to the interests of businessmen and to the outside public generally, but I cannot believe that it would be wise to attempt to start another organization [1, May 24 1915].

At one time, Young admitted, he had believed in the desirability of a purely scientific society of economists; but he now considered that if a limited society were to be formed it should be entirely separate from the American Economic Association, since the latter required at least 2,500 members in order to sustain its current activities and could not, therefore, afford to be selective. Recently, Young continued, he had accepted an invitation to be a "Fellow" of the American Statistical Association, supposedly "a small and select body of statisticians of established reputation," but he doubted the advisability of such a category in economics.

A body like the Institute of Actuaries of Great Britain, or like the American Actuarial Society can set up definite standards for membership, and can even set rigorous entrance examinations. In such a Society a fellowship means something, and has deservedly a real professional value. I doubt very much whether in our field it is possible to set up standards so definite and exact that we can create an organization membership which will in itself be a mark of definite standing and attainments. That seems to be the most substantial difficulty in the way of your plans.<sup>18</sup>

<sup>18</sup> [1, Young to Sakolski, Sep 25 1915]. It may be noted that although the Royal Statistical Society and the British Economic Association both had a constitutional procedure for dealing with the expulsion of undesirable members, neither the American Statistical Association nor the American Economic Association had a comparable procedure.

By a curious coincidence, about a month after his correspondence with Sakolski (which apparently bore no tangible organizational fruits), Young received a letter from E. A. Pratt, Chief of the Bureau of Foreign and Domestic Commerce of the Federal Department of Commerce, who represented the opposite point of view. Complaining that the *Review* contained little of interest to businessmen and non-academic readers, Pratt added:

Please do not interpret this to mean that I discount in any way the value of the university professor and what he has to say, but if you expect to draw business men to your organization, it seems to me absolutely necessary that you have them among your officers, that you put them on the program of your annual meetings and that you publish in your economic review things which would be of interest to them, written by men whose names will carry weight among them, and that you do not absolutely worship the strictly academic [1, Nov 8 1915].

In his reply Young granted the justice of some of Pratt's criticisms and explained:

The difficulty is, of course, that the Association is really trying to do two things at once, that is, to stand as the representative scientific organization of the professional economists, and more especially, the academic economists of the country, and at the same time to gather into its membership men from all walks of life who are interested in any way in practical economic problems. . . . The Association was in its beginnings primarily an academic organization, and I am inclined to think that probably it was wiser that it should remain so. If it should break away from its academic moorings, another Association would probably be formed to take its place. At the same time we do not want to sail under false pretences. This explains my reluctance to try to extend our membership among business men except in so far as they themselves understand our work [1, Nov 11 1915].

To Dewey, Young confided:

I am inclined to think that sooner or later we shall have to face the question of just what kind of an association we want to be. My own efforts, as you know, have been devoted to strengthening our hold upon those persons who might be counted upon to support a strictly professional and scientific association. I do not believe that Babson's efforts among business men have done us any good, for few of his nominees remain members for more than one year [1, n.d. (probably Nov 1915)].

Dewey's reply raised a question of central importance:

I have wondered whether it would be better to have two classes of members, one class for the most part composed of academic members who should pay the full fee of five dollars on the basis of professional interest

and loyalty and the other class of cooperative members who would perhaps pay a smaller fee and would connect themselves rather from public interest, very much as they subscribe for their other objects which are regarded to be for social welfare [1, Nov 15 1915].

The fundamental question of professional identity and standards could not, however, be disposed of so easily, and there is no reason to think that any such modification of the existing egalitarian membership policy would have been accepted at an annual meeting. Too many economists objected strongly to the creation of any special fellowship or other membership hierarchy, because it smacked of oligarchy and might lead to the domination of the organization by one of its constituent groups, such as the nonacademic economists or an Eastern academic elite.<sup>19</sup> In the event, a genuine problem of classification according to professional qualifications and expertise was forced upon the economists by the war, when the A.E.A. committee was asked by the Federal Civil Service Commission to examine 900 cards filled in by economists and statisticians who had expressed their willingness to serve the government. As the President of the Commission wrote:

It is understood that your committee will discard the names of persons who do not properly come within the category of economic expert, will classify under proper headings those who are trained along economic lines, and will make such comment in individual cases as you consider advisable [1, President, U. S. Civil Service Commission to Secretary, Oct 8 1917].

Like certain other delicate constitutional matters that arose during the wartime emergency, the question of the classification of economists did not come to a head, largely because of the speedy and successful termination of the war. In 1919 Abram Berglund of the Tariff Commission sent a report on classification to Young, but by this time the question had become somewhat academic.<sup>20</sup> During the 1920's the problem recurred again from time to time, but no action was taken.

<sup>19</sup> Although the danger of a regional split within the A.E.A. had apparently disappeared by the early 1900's, echoes of the earlier difficulties were occasionally heard, especially in connection with the perennial problem of the location of annual meetings. For example, H. Davenport wrote to Young on May 11, 1914, "it has largely been on the basis of these non-professional members that the large majority of eastern men in the Association has existed, and the right or claim built thereon to have most of the Association meetings take place in the East." In a judiciously impartial reply, Young wrote that the 1914 Handbook "will contain for the first time a geographical index of our membership. This should furnish ammunition for one side or the other" [6, pp. 567-70].

<sup>20</sup> [1, Berglund to Young, Dec 24 1919]. Under each of three broad headings, "Economist," "Agricultural Economist," and "Social Economist," there were five subcategories based on age, academic qualifications, and experience.

By 1924, as the result of another systematic membership campaign, a five-fold classification of members was introduced, but like the conventional distinctions between "honorary," "life," and "ordinary" members, this, too, was based exclusively on financial considerations.<sup>21</sup>

#### IV. *Public Responsibility and Nonpartisanship*

In addition to questions arising from the size and character of its membership and its responsibilities to both academic and nonacademic economists, the officers of the Association were always conscious of their relationship to the general public. The original constitution had stated that, "In the study of the industrial and commercial policy of government we take no partisan attitude," and throughout the period under review serious efforts were made to adhere to this general principle, for nonpartisanship was usually held to be the *sine qua non* of a scholarly and scientific approach to economic questions. In practice, however, this policy was more difficult to execute than might be supposed at first sight, for the organization's officers received many inquiries, invitations, and appeals which made it exceedingly difficult for them to maintain their pose of olympian detachment. If they occasionally strayed from the narrow path of righteousness, it was mainly because they were anxious to demonstrate the economist's importance to the business community and to the general public, for as Ely had frankly admitted when he presented his "Statement of Principles" at the inaugural meeting in 1885, "it is not easy to arouse interest in an association which professes nothing" [10]. These deviations were, of course, especially liable to occur under the leadership of activists like Ely, Carver, and Irving Fisher (who was President of the Association for a time during World War I), and the variety of forms which this deviationism assumed are worth noting because they reveal how varied were the temptations and pressures to which the economists were subjected.

Given the persistent differences of opinion as to what the Association should do, it is hardly surprising to find that there were corresponding differences about what it should not do, and the task of interpreting the "nonpartisanship" clause of the constitution was one to gladden the heart of the most devious of constitutional lawyers. Even Young, who so strenuously upheld the cause of scholarship,

<sup>21</sup> [1, For example, Westerfield to T. W. Page, Mar 26 1924 and Page to Westerfield, Dec 24 1924]. Also the circular to members of May 3, 1924, which was followed by a change in Article III of the Constitution. The new categories were "subscribing" and "contributing" members.

See also [1, T. W. Page to Deibler, Dec 7 1925; Managing Director of the Taylor Society to Secretary, June 23 1926].

proudly proclaimed that the Association had "done as much as any one influence to disseminate sound ideas on many economic problems";<sup>22</sup> but he would hardly have agreed with Carver that its "main purpose" was "to run the affairs of the country in an economical and progressive way" [1, Carver to J. E. Woodbridge, Jan 30 1912]. In some cases, of course, there was no difficulty in deciding on the appropriate course of action. The Secretary merely refused to assist those inquirers who wanted to know how to organize birth control education and research, or how to use Fuller's Earth, and he flatly told one correspondent that the A.E.A. took no official position on either the tariff question or the forthcoming presidential election.<sup>23</sup> On other occasions a request that the Association should "probe a little into the alcohol problem" from the standpoint of "pure scholarship" was rejected, and an invitation to join the opposition to a law which would have permitted the importation and dissemination of literature on contraception was refused;<sup>24</sup> but some problems could not be dealt with so easily.

One group of problems arose in connection with the appointment of official representatives to attend conferences or meetings sponsored by other organizations, and here the policies of the Executive Committee demonstrated remarkable inconsistencies. As the Secretary explained to a member on one occasion,

In 1907 . . . [Jeremiah W.] Jenks, then President, by authority of the Executive Committee, appointed delegates to the National Peace Conference. At this very same meeting of the Executive Committee it was voted impossible to cooperate as an Association with the Anti-Child Labor movement. I have also been informed that at a preliminary meeting of those interested in the Conservation of National Resources our Association was represented. If so the representatives were appointed by the President on his own responsibility. At the November meeting last year of the Executive Committee this very Association requested us to appoint representatives to cooperate with that movement. The explicit request for cooperation caused the Committee to decline the request. At that time Professor J. B. Clark argued that if our appointment of representatives were confined to their appearance in the role of interested

<sup>22</sup> [1, Young to A. Belmont, Mar 25 1915]. Young argued that the A.E.A. had made especially valuable contributions to the subjects of money, credit, and banking.

<sup>23</sup> [1, W. S. Reynolds to Secretary, Dec 13 1928; Secretary to Reynolds, Dec 20 1928; A. E. Carman to Secretary, Dec 3 1928; H. Clews to Secretary, Sep 24 1912; Secretary to Clews, Sep 20 and 30 1912]. Mr. Clews, a New York banker, had been asked if he would allow his name to be used on a circular letter to be sent to prospective members.

<sup>24</sup> [1, W. E. Johnson (editor of the *Standard Encyclopedia of the Alcohol Problem*) to Secretary, Jan 16 1905; Secretary of the National Catholic Welfare Conference to Deibler, Nov 18 1925]. In his reply of Nov. 23, 1925, Deibler offered to bring the matter before the Executive Committee but predicted that they would refuse to act.

inquirers merely, we might legitimately appoint delegates. To this view Judge Dill [a Vice-President of the A.E.A.] replied that the appointment of delegates, no matter what the intention, would be construed as sympathetic cooperation. The vote seemed to imply that Judge Dill's opinion was the prevailing one.<sup>25</sup>

Apart from the immediate question whether a delegate might be regarded as a passive observer or an active participant in the proceedings of the sponsoring body, there was the question whether an individual member or group of members could, under any circumstances, be held to commit the Association, *as an Association*, to support or oppose any policy position. In 1928, Fred M. Taylor, then President of the Association, turned down an invitation to become a Vice-President of the Stable Money Association mainly on the grounds that "I have for many years been an almost fanatical supporter of the doctrine that professors as such should keep out of all propaganda work,"<sup>26</sup> and this decision was fully consistent with the action taken by the Executive Committee a year earlier, when it had refused to hold a joint session with the Stable Money Association because the latter "was carrying on a campaign of education or propaganda, rather than constituting a scientific body, like other allied associations."<sup>27</sup> But although Young had informed a critic in 1916 that the A.E.A. was "debarred by its constitution from taking any position on any *disputed* economic problem,"<sup>28</sup> this did not mean, as some cynics might suppose, that the Association was thereby required to remain totally inactive in the field of policy. Among "safe" issues there were such

<sup>25</sup> [1, Acting Secretary of the A.E.A. to Dewey, Jan 23 1909]. (Dewey was then President of the Association.)

<sup>26</sup> [1, F. M. Taylor to N. Lombard, Jan 14 1928]. The leaders of the Stable Money Association included such prominent economists as I. Fisher and J. R. Commons.

<sup>27</sup> [1, Deibler to H. G. Moulton (Director of the Brookings Institute of Economics), Dec 3 1927; T. S. Adams (President of the A.E.A.) to Lombard, Nov 10 1927; Moulton to Adams, Dec 8 1927].

A similar problem arose in connection with other policy-oriented associations, such as the American Association for Labor Legislation, but, as Adams explained to Moulton, the A.A.L.L. had begun as an offshoot of the A.E.A. and its place on the latter's programs had been established by an "old precedent" [1, cf. Ely to Fisher, Jan 24 1919]. An account of the relationships between the A.E.A. and other associations must be deferred until another occasion.

<sup>28</sup> [1, Young to S. H. Pomeroy, Oct 23 1916, italics supplied]. Pomeroy had responded to an invitation to become a member by inquiring "I would ask why you bob up at Election times with your solicitation when your support of levelling wages is so antagonistic to our general welfare. Drop ambiguities and tell me how this country can thrive without a tariff to be made high or low to correspond with the differences in wages in this country and abroad" [1, Pomeroy to Secretary, Oct 18 1916].

On one occasion Young went even further, asserting that "the A.E.A. is prohibited by its constitution from taking any attitude whatsoever on any public question" [1, Young to A. B. Parker, Feb 13 1920].

matters as opposition to a rise in postal rates on the publications of scientific societies<sup>29</sup> and periodic demands for federal aid to American scholars participating in international scholarly and scientific conferences;<sup>30</sup> and during World War I the economists went far beyond the strict constructionist position adopted by Secretary Ray B. Westerfield who, in 1925, replied to a seemingly innocuous Department of Commerce request for an official comment on "the values of simplification in our present industrial and commercial situation" by stating that the A.E.A. was "not interested in propaganda."<sup>31</sup>

During the war, the Association endeavored to do its bit by assisting in the classification of economists who offered to work for the federal government, by inaugurating a scheme designed to coordinate research activities, and by publishing a number of bulletins and special studies of current economic problems. These were but natural responses to the needs of the time, but under the exuberant leadership of Irving Fisher and others, the Association took a number of steps which might, in the long run, have seriously undermined its customary policy of impartiality and detachment. Of these one of the most interesting was Fisher's appeal on behalf of the Thrift Campaign sponsored by the War Savings Committee of the U.S. Treasury, under the chairmanship of Frank A. Vanderlip. According to a circular signed by Fisher which was distributed to all members:

At the Philadelphia meeting a Committee on the Purchasing Power of Money in Relation to the War was appointed. In accordance with the vote at that meeting, this committee, with the authority of the Executive Committee, *but without committing the Association as such*, is publishing a series of bulletins. A copy of the first of these is enclosed. This bulletin was issued through Mr. Vanderlip's Committee, which prepared the introductory statement. It was sent to 20,000 newspapers but was not widely utilized, one reason being that many newspapers could not afford

<sup>29</sup> [1, Editor-in-Chief of *Engineering News* to Secretary, Dec 21 1916]. Young replied on Jan 24 1917, "if a protest will be of any avail at this time I should be glad to enter one for myself *and for the Association* and to ask others to co-operate." (Italics supplied.)

It is amusing to note that the Association's determined effort to be regarded as a scientific society bore unexpected fruit when its members were denied the standard reduction of railroad fares accorded to members of "educational" organizations.

<sup>30</sup> A resolution to this effect was passed at the Minneapolis meeting in 1913 and again at the 1924 annual meeting.

On another occasion the Secretary suggested that although the Association could not "take a stand" on the question of changes in the copyright law, he could insert a statement in the *Review* advising interested members to exert pressure on their Congressman [1, Westerfield to M. L. Rainey, Jan 9 1923].

<sup>31</sup> [1, Secretary, Department of Commerce, to Westerfield, Apr 4 1925; Westerfield to Dept. of Comm., Apr 14 1925]. Westerfield's response was somewhat surprising in view of the Association's earlier cooperation with federal departments, especially in connection with the Census.

to antagonize advertisers of non-essentials. This obstacle emphasizes the very real need of the intelligent and patriotic help of economists.

. . . Any suggestions as to further committees which might be appointed or as to activities in which the Association or its members might engage which would be of value to the country in the present crisis, would be greatly appreciated.<sup>33</sup>

From the constitutional point of view, the crux of the matter was the almost scholastic distinction contained in Fisher's introductory observation: "As you know, the Association, *as such*, does not engage in propaganda. The appeal is to the members individually,"<sup>33</sup> for this rubric could be used to cover a multitude of sins. The best example of the dangers of this distinction is provided by the postwar enthusiasm for the peace movement. Although the executive committee was reluctant to give an open vote in favor of the League of Nations' Resolutions, it recommended the incoming President (H. B. Gardner) to "submit them to each individual member with any recommendation he might care to make."<sup>34</sup> In response to this request, a circular signed by Gardner was dispatched to all members stating:

In accordance with established precedent no action in the name of the Association was taken by the Association or its Executive Committee, but there was a general feeling that the matter was of such great importance that it should be brought to the attention of the individual members of the Association. Fully concurring, as I do, in this feeling, I herewith transmit the resolutions and urge each member of the Association to immediately express his convictions on the question to the congressmen and senators from his state.

While action in the name of the Association is open to objection, there is no question that the membership of the Association should make its influence felt in the decision of a question of such tremendous importance not only for our own nation but for the future of the world.<sup>35</sup>

<sup>33</sup> [1, Fisher to members, Mar 9 1918, italics supplied.]

<sup>34</sup> *Ibid.* (Italics supplied.)

<sup>35</sup> [1, Fisher to Gardner, Jan 21 1919]. On Jan 2 1919, Fisher had explained to Gardner, in a letter informing him of his election to the Presidency of the A.E.A., "it was thought best by the Executive Committee not to pass it, partly because of our precedents and partly because we did not think the resolution would be as effective as individual letters." Gardner could, if he wished, express his own opinion. "In any case, it would not commit the Association as such."

<sup>36</sup> [1, Gardner to members, Feb 11 1919]. The resolutions advocated the establishment of a "League of Nations to enforce Peace and Justice throughout the world," and asserted that "we favor the entrance of the United States into such a League of Nations as may be adequate to safeguard peace." As a sequel to this incident, in January, 1921, the A.E.A. received urgent requests from William Howard Taft, President of the League to Enforce Peace, asking them to send two representatives to a national meeting in Washington, but there is no evidence that this request was granted. Possibly by this time the sense of emergency had passed and strict constitutionalism reigned once more. In 1923 the Asso-

Presumably, when the future of the world was at stake, it was permissible to stretch the A.E.A. constitution to its limit; but it has been well said that of all constitutional arguments the most damnable is that of emergency, and, in taking such liberties with its customary practices, the Association was running a considerable risk. Apparently the gamble was successful, for there were no protests and this proved to be an isolated incident. There were, however, some who doubted the advisability of the activist policy undertaken during the war itself.

One of these cautious spirits was Frank A. Fetter, an erstwhile Secretary and President, who was always sensitive to the scholarly and scientific properties. Even at the height of the wartime enthusiasm he wrote:

I hope that the committee on prices will be restricted to the field which, as I understand it, the Executive Committee meant to authorize it to survey—viz. the problem of price inflation in this war. It will be *ultra vires* and will involve the Association in activities contrary to our constitution if it tries to wander over all creation and to direct the general economic policies of the nation in this whole war [1, Fetter to Young (n.d.), 1918].

The kind of danger that Fetter envisaged was revealed in a statement published by one A.E.A. committee which announced that its work was

... intended to put into popular language some of the simple economic principles or *precepts* connected with the Purchasing Power of Money, and particularly to emphasize the importance of saving money with which to buy Liberty Bonds and pay taxes instead of lending to the Government merely what we borrow of the banks, which procedure is apt indirectly to raise commodity prices.<sup>30</sup>

To those members who feared that such publications would commit the Association, *as an association*, to any given policy recommendations there was, of course, a standard reply, namely that the reports of A.E.A. committees did not constitute official policy positions, but merely the views of the authors. This position was consistently maintained, as for example in the Secretary's report of 1900, which stated rather vaguely that "the Association vouches for [a report] as far,

---

ciation refused to allow the American Peace Award to ballot its members in connection with a national referendum on the question of a plan for international peace. [1, Secretary to American Peace Award, Jan 3 1924].

<sup>30</sup> [1, *italics supplied*]. A copy of this statement approved by the Committee on the Purchasing Power of Money is in the 1918 file.

and no further, than for the works of other authors which it issues,"<sup>37</sup> or, as in a secretarial letter of 1926, that

The responsibility for the ideas contained therein rests entirely with the individuals who draft these reports and cannot, in fact, be said to express the attitude of the Association, as an organization. Any expression of opinion contained in such reports must stand on their own merits.<sup>38</sup>

Nevertheless, as Judge Dill remarked in connection with the appointment of representatives as observers of or delegates to other organizations,<sup>39</sup> despite the Association's good intentions it seems likely that most readers attached much more weight to an authorized report signed by a number of leading economists, especially when it was circulated by a government department, than to a regular leading article in the *Review*.

During and after the war, on the crest of a wave of enthusiasm for empirical research, there was a lengthy discussion of various prospects to establish links between the American Economic Association and the Institute for Economic Research (usually known as the Brookings Institute). Initially there was some possibility that the Association might sponsor or even found such an institution;<sup>40</sup> but long after the Institute had been inaugurated with the aid of funds provided by Robert S. Brookings, it was suggested that the A.E.A. should establish its permanent office in the Institute's building in Washington [1, cf. H. Seager (President of the A.E.A.) to Westerfield, Nov 10 1922]. Even in the 1890's, the desirability of such an office and a paid secretary (on the lines of the American Historical Association) had been debated, but although the matter was still under consideration as late as 1928, no action was taken,<sup>41</sup> and the Secretary's office has retained its present location at Northwestern University since 1925. As always, one of the main reasons for the Association's reluctance to identify itself with another body, even a reputable independent research or-

<sup>37</sup> [2, pp. 47-48]. The occasion was the publication of a volume of *Essays in Colonial Finance*, with the aid of funds subscribed by W. E. Dodge, T. Marburg, I. N. Seligman, S. Wood, and the late T. G. Shearman. From time to time other businessmen provided funds for similar purposes.

<sup>38</sup> [1, Secretary to R. C. Reusch, Dec 7 1926]. He explained that the publications of the War Finance Committee (1919) were "the only expression of opinion [on the subject of the issuance of war bonds] that could be regarded as the attitude of the A.E.A."

<sup>39</sup> *Supra*, p. 277.

<sup>40</sup> [1, See the report by E. D. Jones submitted to Young, dated Dec 9 1919. Also W. H. Hamilton to Jones, Nov 18 1919; Fisher to Gardner, Jun 4 1919.]

<sup>41</sup> [1, See, for example, Deibler to T. S. Adams, Jan 7 1928, and Oct 12 1928; Deibler to Dewey, May 8 1928; Dewey to Deibler, May 21 1928; E. C. Day to Deibler, May 28 1928.]

ganization, was the fear that this might in some sense commit the American Economic Association to support of the findings of the Institute's publications. This concern was fully revealed in 1925, when a proposal to launch a large-scale investigation of "the present method of industrial price fixing and price quotation in relation to economic theory" was advanced by H. Parker Willis.<sup>42</sup> This was not the first proposal of its kind; and during the war clear precedents in favor of such a scheme had been established. Nevertheless, many prominent members were opposed to it for a variety of reasons. Allyn Young (then President of the A.E.A.), for example, considered that "there are a hundred other questions of equal importance. I believe it to be particularly unwise that the Association should have any direct connection with the investigation of any one economic problem, no matter how important." Carl R. Plehn held that the Association "should not lend our name and become morally responsible without control," and considered that the wartime undertakings were "exceptional." And even Thomas W. Page, who was President of the Institute for Economic Research and a long-standing member of the Association, expressed his inability to understand "how such an investigation could be undertaken by an independent agency subject to the approval and under the direction of a special committee of the Economic Association. I see no harm in conferring with such agencies as may be deemed competent, but I gravely doubt whether any satisfactory arrangement for cooperation can be made."<sup>43</sup>

As it transpired, no investigation was undertaken, mainly because neither the Institute nor any other suitable research body was able to provide the requisite services on terms within the Association's financial means. Here, as elsewhere, the outcome of long deliberation was dictated as much by fortuitous circumstances as by sensitivity to fundamental questions of principle; but there seems little reason to doubt that the strong opposition to any active A.E.A. intervention in questions of current economic importance was a significant factor in the situation.

<sup>42</sup> [1] This is cited from Willis' motion, as amended by J. R. Commons, and submitted to the Executive Committee in December, 1925.

<sup>43</sup> See Young's handwritten comment on the back of a circular dispatched to members of the Executive Committee [1, Jan 23 1925; also Young to Westerfield, Feb 18 1925; Plehn to Westerfield, Feb 16 1925; also Page to Westerfield, Jan 29 1925]. Plehn also added: "The subject is hot with controversy. Hence any advisory committee should see that its proceedings are of record in such a manner as to clearly show how far it took responsibility, if at all. That 'if at all' means that in my own opinion a *competent* bureau would prefer to assume full responsibility." (Italics in original.) Some members of the Committee either expressed no opinion or raised no objections to the proposal. For the final outcome, see Young's undated circular to members of the Executive Committee [1, (c. Oct 1925) and Deibler to Young, Oct 29 1925].

Finally, under the general heading of policy questions, the conduct and content of the annual meetings of the Association were occasionally the subject of heated controversy. According to the activist view propounded by Carver and others, the selection of topics and speakers assumed almost legislative proportions for, as he informed one U.S. Senator, "all sorts of public measures are discussed, and we try in that way to influence public opinion, but not by officially endorsing a measure by any formal vote [1, Carver to C. S. Page, Oct. 2 1912]. Obviously the program of the annual meeting does afford some guide to the subjects deemed worthy of engaging the members' time and attention, and it is incumbent upon the organizers to secure competent and representative speakers. But in the period under consideration highly topical and controversial matters were sometimes discussed by spokesmen of various interest groups or by economists engaged in studying these questions, and there were inevitably some occasions when critics complained that the organizers had failed to provide a properly balanced treatment of the issues at stake.<sup>44</sup> The planning of the annual meetings, therefore, came to be regarded as yet another matter in which it was vital that the Association should adhere to a policy of strict neutrality.<sup>45</sup>

#### V. *The Attainment of Financial Independence*

The final episode of this story exemplifies the perennial interaction of the forces of continuity and change in historical narrative. Like other scholarly associations in the United States and elsewhere, the war brought a serious setback in the Association's finances owing to a fall in membership income and a sharp rise in costs, and consequently in the early 1920's a third, and what has proved to be a final, membership campaign was undertaken. Once again the funds were provided by a group of businessmen who, as earlier, had been persuaded by a few wealthy academic economists to come to the Association's rescue.<sup>46</sup> Once again a Membership Committee was estab-

<sup>44</sup> See, for example, J. D. Hubbard, a Chicago employer, who appeared on a "Closed and Open Shop" panel discussion in 1904, and subsequently complained bitterly that most speakers were biased against employers: "As a fair and open discussion, the Symposium must be deemed an absolute failure," [1, Hubbard to Taussig, Dec 31 1904]. Similarly, with reference to the representativeness of H. C. Adams' views on public utility corporations see [1, H. T. Newcomb to Dewey, Sep 7 1909].

<sup>45</sup> As in very recent years, there were periodic complaints that the same names appeared too often on the annual programs and that young men and lesser-known (especially mid-western) institutions were underrepresented [1, Cf. Fetter to Taussig, Aug 28 1905; J. H. Raymond to Carver, May 1 1912; Deibler to H. H. Burbank, Oct 12 1925].

<sup>46</sup> [1]. In January, 1919, the Association received \$5,000, the outstanding balance of a sum of \$20,000 which had been provided to support the publication of studies in war finance, and in September, 1922, a special finances subcommittee was set up under the

lished (which included Roger W. Babson), and energetic solicitation among nonacademic as well as academic groups produced a large crop of new recruits.<sup>47</sup> This time, however, the American Economic Association was incorporated in Washington in 1923; a permanent endowment fund was raised with the aid of established members and interested outsiders; and the investment of these funds subsequently formed the basis of the Association's now almost indecently healthy capital position.<sup>48</sup>

There were, of course, favorable external conditions that contributed to this happy solution of the Association's bread and butter problems—especially the contemporary prosperity of business, and the growing number of full-time economists employed by universities, colleges (especially Schools of Business), business enterprises, government agencies, and independent research institutions. By the second half of the 1920's the organized economists had, in effect, succeeded in raising themselves by the businessmen's bootstraps to an enviable position of independence, a position which their predecessors had for so long unsuccessfully striven to attain. Naturally there were still some delicate policy problems to be decided, and, as previous paragraphs have indicated, the variety of needs and interests of the Association's membership meant that its officers were never able to satisfy all of their constituents all of the time.

Nevertheless, in the years before the impact of the Great Depression was felt, the American Economic Association finally managed to consolidate and husband its resources and had at last reached its long-delayed maturity.

## THE DEPLETION ALLOWANCE IN THE CONTEXT OF CARTELIZATION

By ALFRED E. KAHN\*

The economic commentary on the special tax privileges accorded our extractive industries, most importantly oil and gas, has increased sharply in both volume and rigor in recent years, despite the apparent political immovability of the object of all this attention. Meanwhile a far more extensive literature has accumulated over the last several decades concerning the peculiar market structure and performance of the oil industry, and in particular its combination of state production control and import limitations, which in the name of conservation and national security, respectively, in effect organize the industry into a cartel; the relatively moderate concentration in a domestic market crowded with huge vertically integrated firms; and, more recently, public regulation of the price and interstate sales of natural gas.

In my judgment, the literature and public debate in the first category have for the most part failed to make systematic contact with the second—and conversely. The “industrial organization” studies in general do not give careful analytical consideration to the economic consequences of the depletion allowance (to use a short-cut expression for a more complex phenomenon);<sup>1</sup> and almost without exception, to my knowledge, the “public finance” literature has inadequately considered the implications and merits of the tax arrangements in the light of the comprehensive cartelization of the crude oil market. (For one outstanding exception, see [37].) The present paper attempts to remedy the latter omission.

Paul Davidson has taken several important steps in the direction of bridging this gap, less by actually constructing the necessary links than by incorporating in one article a consideration of (a) the allocative effects of the tax preferences, (b) the impact of production control on the time pattern of resource utilization, and (c) the effect of the tax system on the motivations of vertically integrated companies

\*The author is professor of economics at Cornell University. He wishes to acknowledge with gratitude the criticisms of C. H. Berry, M. G. de Chazeau, J. B. Dirlam, P. T. Homan, S. L. McDonald, B. C. Netschert, G. J. Staller, and the especially painstaking and searching comments of his colleague, R. W. Kilpatrick.

<sup>1</sup>For convenience we will continue to use this rather loose characterization of an inter-related bundle of tax provisions, described more precisely in Section I, below.

with respect to the pricing of crude oil [7]. After a brief description of the relevant tax provisions, the present paper begins by examining the Davidson argument that the benefits are eaten up entirely by economic rents. Then, having rejected the view that the allowance does not significantly affect investment, it summarizes and appraises various arguments about whether the stimulus it imparts to investment contributes positively or negatively to the neutrality of the tax system. These arguments, it will demonstrate, virtually ignore the peculiar structure of this industry and, because of this, often go astray in identifying the effects of the allowance. The article then attempts to demonstrate explicitly the bearing of prorationing and import restrictions on the allocational and national security defenses of these tax provisions.

### I. *The Relevant Tax Provisions*

The most important privileges available to recipients of income from oil and gas production<sup>2</sup> involve three options that must be considered together: (a) to charge against income from any source, in the year in which they are incurred, the major investment expenditures—for dry holes and the intangible costs of drilling and equipping productive wells;<sup>3</sup> (b) to compute depletion expense on either a cost

<sup>2</sup> These include landowners, on whose bonuses and royalties percentage depletion may be taken [17, p. 1482] [30, p. 375] [4, p. 375, n. 63].

<sup>3</sup> In the legal sense, the option of charging off dry-hole costs is not a privilege peculiar to oil; the treatment is analogous to that of research expenditures, for example. On the other hand, to accord this treatment to the intangible costs of productive wells is clearly a special privilege in every sense. In any event, the discrepancy between what the economist and the tax collector define as capital expenditures is clearly extraordinarily large in this industry. The industry's domestic expenditures in 1959 and 1960 for exploration and development, exclusive of overheads, were estimated by the *Joint Association Survey* [58] as follows (in \$'000,000):

	1959	1960
Exploration		
Dry-hole costs	821	774
Lease acquisition	554	626
Geological and geophysical	320	277
Lease rentals	193	193
Other	124	175
Total	<u>2,012</u>	<u>2,045</u>
Development		
Producing wells	1,830	1,651
Equipping leases	483	431
Total	<u>2,313</u>	<u>2,082</u>

The dry-hole costs and most of the rentals are deductible expenses. Those of the geological, geophysical, and other expenses that do not eventuate in acquisition of leases can be similarly written off; the remaining portion, and the lease-acquisition costs themselves, both of which must be capitalized, can be written off as ordinary losses when a lease is

basis or as  $27\frac{1}{2}$  per cent of gross revenue up to 50 per cent of net income from the property;<sup>4</sup> (c) to report as capital gains the proceeds from the sale of producing properties net of whatever costs remain not previously charged off.<sup>5</sup> It is the combination of (a) with (b) that grossly inflates the tendency of the latter to permit companies to recover more than original investment cost free of tax: when the major costs have already been charged against income, the option thereafter to take depletion as a percentage of revenue without regard to costs becomes correspondingly attractive.<sup>6</sup> Conversely, (a) alone, like any accelerated amortization, would permit an alteration only in the timing of tax, amounting to an interest-free loan to the taxpayer; but combining (a) with (b) tears up the promissory note. Similarly the combination of (a) with (c) permits the operator first to reduce his tax by 52 per cent (at the corporate rate) or up to 91 per cent (at the individual rate) of the capital expenditure; then to pay a maximum tax of 25 per cent on the return of these outlays when he sells the property.<sup>7</sup> Moreover, the availability of option (c) represents an alternative, for the explorer, to operating the property himself and availing himself of (b). Any diminution of (b) could therefore be in large measure evaded if route (c) remained open [30, pp. 377-79]. On the other side, the buyer can afford to pay a

---

abandoned [17, pp. 1481-82] [4, pp. 375-80, 513-16]. Of the development costs, estimates of the intangible portion—i.e., those expenditures that do not produce salvageable assets—run from 50 to 75 per cent, with 60 per cent perhaps the most reasonable approximation. (Interviews by H. Peter Burckmeyer (unpublished); also [25, p. 1021]). For estimates of the combined importance of these options, see Steiner's survey [46, p. 960]. All of these options are typically taken.

<sup>4</sup> McDonald and Galvin supply lucid descriptions of these options [28, pp. 325-27] [17, pp. 1463-65]. In practice the net income limitation does reduce the percentage depletion actually taken. McDonald estimates effective depletion in the industry is around 22 per cent, and its net benefit as compared with cost depletion around 20 per cent, of gross revenue; in his judgment the figure would be lower if information were available for firms reporting net losses for income tax purposes [28, pp. 328-29]. On the problem of defining the property unit, see n. 18, below.

<sup>5</sup> The last, again, see n. 3, above, is not technically a special privilege unique to extractive industries. But it is peculiarly important in oil.

<sup>6</sup> Moreover, to the extent the investment costs are not chargeable to particular producing properties (e.g., exploratory dry holes), or are charged off before production begins, they reduce the constricting character of the 50 per cent-of-net-income limitation, for net income to this extent tends to approach gross. The President's 1963 tax proposals sought to reduce this opportunity of escaping the 50 per cent limit by requiring that all such deductions attributable to particular producing properties be carried forward and counted as expenses in computing net income after production commences [52, pp. 17-18, 108-10].

<sup>7</sup> The President therefore proposed in his 1963 tax message that the portion of gross receipts equivalent to costs (including depletion) previously charged off against income be taxed at ordinary income tax rates [52, pp. 18, 136-38]. The House Ways and Means Committee first adopted a limited version of this proposal, then rejected it entirely [*Wall Street Journal*, June 18, 1963, p. 4; Aug. 6, 1963, p. 3].

price high enough to remunerate the discoverer for giving up option (b) because he can, as in any other industry, write it off on a cost-of-acquisition basis, regardless of how much of the original cost the discoverer has already charged off under (a).

## II. *The Effect on Supply: A Preliminary View*

### A. *The Long-Run and Economic Rents*

Davidson's argument, it will be recalled, is that the contribution of percentage depletion to investment is slight or nil<sup>8</sup> because its benefits go primarily or entirely into economic rents. And this is so, he avers, because the supply of uncommitted oil leases is completely inelastic. If this reasoning were correct, it would make practically superfluous all further serious consideration of the merits of the allowance.<sup>9</sup> Duncan R. Campbell has, in my opinion, supplied the appropriate refutation—that Davidson's reasoning would be valid only if all potentially oil-bearing lands were homogeneous in quality[6].

If the total supply of potentially oil-bearing leases were both homogeneous and completely inelastic, there would be no rents paid today at all—oil leases would be a free good—since market demand does not intersect any such supply schedule at any point.<sup>10</sup> Most potentially oil-bearing land is in fact not under lease at any rent; and some of the land that is under lease commands very high rentals. Rents are paid because these lands are nonhomogeneous, so that the fixed and inelastic supplies of leases of certain degrees of attractiveness are indeed intersected by derived demand curves (while others are not). And rents on such inframarginal lands rise as the margin of cultivation is extended downward and outward by application of additional real resources to exploration and development. It is precisely *because* and *as* provision of a tax subsidy hastens this process that it increases rents.

Still, Davidson is certainly right to point out that whatever economic case may be made for these tax concessions is weakened to the extent that they merely increase rents. The effects of the subsidy on supply, on the one hand, and rent, on the other, are mutually an-

<sup>8</sup> Compare [6] [7, pp. 86, 104, and 106] [8]. A nil effect would seem to follow from his assertions about the perfect inelasticity in the supply of presently uncommitted lands.

<sup>9</sup> Cf. Steiner: "virtually everyone concedes that present tax concessions do stimulate production and income (and thus induce a higher level of investment and production)." [47, p. 951, n. 6].

<sup>10</sup> According to A. D. Zapp, it is unlikely that more than 20 per cent of the drilling required "for even near-exhaustive exploration" of the area "that has favorable prospects for the discovery of petroleum" has as yet been done in the United States, even excluding Alaska and strata below 20,000 feet [56, pp. H-23-24].

tagonistic—the more it increases the one, the less it increases the other. How far, if at all, it moves the supply curve to the right, rather than increases rents, depends directly, as Stephen L. McDonald has pointed out in a related connection, on the elasticity of supply of oil as determined by the continuity and slope of the “curve of land quality gradations” [30, p. 376]: the more readily available are submarginal prospects of not much poorer quality than those currently at the margin, the more will the subsidy shift the supply of oil to the right, and the less will it increase rents. In McDonald’s judgment this “gradient of alternative site qualities” is gentle; he therefore attaches little importance to the effect of the allowances on rents.<sup>11</sup>

An indirect reflection of the relative importance of these two opposing tendencies is provided in the size of rental payments in this industry. In 1959-60 about 18.5 per cent of its total capital expenditure was merely payment to landowners for the right to probe beneath their soil (see note 3, above). In addition, some 15 per cent of the gross receipts from oil and gas production went in royalties [58]. Appropriately adjusted, these two can be added; a reasonable approximation might be that 25 to 30 per cent of the industry’s gross revenues, hence 32 to 38 per cent of its value-added, represented economic rents.<sup>12</sup> This estimate suggests that the slope in the qualities of

<sup>11</sup> See [30, p. 376] and [29, p. 322, n. 29]. Actually McDonald’s discussion pertains to the relative impacts of the corporation income tax and percentage depletion on rents on the one hand and *price* on the other. He therefore introduces as the second determinant the elasticity of demand for oil and gas. His judgment that this elasticity is low reinforces his view that the allowance does much more to decrease price than to increase rent.

<sup>12</sup> See the estimates, of similar dimensions, by Bain [2, pp. 80-84]. The rough estimate in the text is based principally on computations made for me by Martin Bernstein, of National Economic Research Associates, Inc., from statistical summaries of the detailed reports supplied for 1960 by producing companies in the Permian Basin to the Federal Power Commission (*In the Matter of Area Rate Proceeding, et al. [Permian Basin Area]*, Docket No. AR 61-1, *et al.*, Exhibits 142, 149, 153 and 154). Total net working interest revenue of the reporting companies was about 60 per cent of the industry-wide total estimated by the *Joint Association Survey*. The rents are computed as including (1) royalties, estimated, following the JAS, at 15 per cent of gross revenues; (2) cancelled, surrendered, and abandoned leases (i.e., charged off against income in 1960), with a rough adjustment to take out some capitalized geological and geophysical expense associated with the abandoned leases; (3) amortization of nonproducing leases; (4) lease rentals and options; (5) (cost) depletion charged on producing leases; and (6) a share of net income before federal income tax, proportional to the share that net investment in producing and non-producing leaseholds constituted of total net investment. The total of these items amounted to approximately 30 per cent of estimated gross revenues.

I have chosen to state the figure rather at 25 to 30 per cent because it would appear the above computations must involve counting the costs of leases acquired by one producing company from another, in which event there are included among rents some reimbursements of costs of a nonrent character (e.g., of dry holes and of a return on investment) incurred by the original exploring company.

potentially oil-productive land is far from gentle: so do the average bonuses of \$233 to \$2,267 per acre offered by successful bidders for federal leases in the Gulf of Mexico in auctions held in the 1959-62 period.<sup>13</sup> Clearly the market at any given time places a far higher valuation on *some* intra- than on extra-marginal land. This does not prove that there is a steep slope at the margin itself, within the range affected by the depletion allowance; but the height of total payments suggests that a large part—I lack the information required for greater specificity<sup>14</sup>—of the tax benefit goes to swell rents, and a correspondingly reduced part into expanding productive capacity.

At the same time, as we will argue more fully below, the depletion allowance does make an important contribution to increasing the real exploratory and developmental effort, and thus (to a lesser extent) to increasing productive capacity. We therefore turn, in Section III below, to the question of whether the increase in rents may not be a necessary price for achieving the optimal allocation of resources into this industry.

### B. Short-Run Shifting

Davidson recognizes that his argument about economic rents does not apply (equally) to presently producing properties. The terms of their leases having already been fixed, any additional tax incident to

---

The adjustment to the value-added basis is derived from the ratio of value-added to total value of shipments and receipts in 1958 [60, 1961 ed., p. 254].

Thus, it would appear, there is some exaggeration in Davidson's assertion that "the major costs in oil exploration and development are economic rents" [7, p. 103]. The exaggeration apparently resulted from adding together the industry's annual royalties, which averaged about \$1,370 millions in 1959-60 [58], and lease-acquisition costs and rentals, and comparing that total with the industry's total exploratory and developmental outlays (see n. 3, above). This addition leaves out of account the sharp difference in the distribution of the two kinds of payment over time. Royalties are paid out of revenues (which averaged \$9.1 billions in 1959-60, according to the JAS) over the producing life of the properties.

<sup>13</sup> *Petroleum Press Service*, Sept. 1959, p. 363; April 1960, pp. 149-50; also [45, p. 0 38]. Moreover, offshore royalties are fixed at  $\frac{1}{6}$  rather than the typical  $\frac{1}{8}$  of gross revenues (*Oil and Gas Jour.*, April 1, 1963, pp. 78-79). The fact that the principal explanations of the highest bonuses are the nearness of the leases in question to known producing formations—knowledge of what lies beneath the surface may be a more important aspect of a lease's economic quality than its "original and indestructible powers"—and, on federal leases, the prospect of being able to operate as a unit any reservoirs that may be discovered in no way vitiates the observation that the economic quality of such leases is far higher than of submarginal ones.

<sup>14</sup> The preliminary results of a study by Franklin Fisher for Resources for the Future indicate strongly a far greater price elasticity in the supply of exploratory effort than of actual discoveries. These findings, if substantiated, provide specific and direct validation of the inference drawn here. They also illuminate the other side of the coin: the diminishing returns, hence the rising real unit costs, attributable to a subsidy that shifts the margin of cultivation outward.

reduction of the depletion allowance could not (in full measure) be shifted back to their owners.<sup>15</sup> Thus withdrawal of the allowance might, like the imposition of an excise tax, tend to shift the industry's short-run supply curve upward.<sup>16</sup> He deprecates this possibility, however, for two reasons: first, that any resultant tendency for product prices to rise would generate pressures to relax import quotas and state production controls; and, second, that the effect would also be to force the abandonment of some high-cost wells, in consequence of which production allowables for the typically lower-cost, controlled wells could be increased: "thus, the short-run supply curve of the industry could shift outwards rather than upwards" [7, p. 106].

The virtue of this reasoning is precisely that it attempts to analyze the effects of the tax in the context of the industry's cartelization. But, unfortunately, it is much more difficult to predict the reactions of a politically directed cartel than of a profit-maximizing entrepreneur. My own judgment is that, for the following reasons, withdrawal of percentage depletion (a) would not significantly move short-term supply curves to the left, (b) would certainly not move them to the right, (c) would have a more marked effect in curtailing intermediate and long-run capacity, and (d) could well provide the pretext, though hardly an economic justification, for an early price increase.

1. Production from so-called marginal or stripper wells accounts for only about one-fifth of the national total [60, 1961 ed., pp. 33-34]. And most of these are almost certainly not marginal in the economic sense: probably only a very minor proportion would shut down or even appreciably reduce output if the effective price declined from, say, \$3.43 to \$3.00.<sup>17</sup>

<sup>15</sup> I have added the parenthetical qualifications in recognition of the fact that the portion of rent taking the form of royalties is a variable cost (see [7, pp. 90-91]) and can be sloughed off by a failure to continue production or to develop these properties. If, because of a reduction in the depletion allowance, gross revenues (after tax) cease to be large enough for the portion of them remaining with the operator, net of royalty, to cover the relevant incremental costs, the landowner will bear part of the burden.

<sup>16</sup> Davidson's excise tax analogy is extremely illuminating in explaining how an alteration in the effective tax on net income can alter short-term production decisions, something that is at first blush difficult to credit. The reason is that the depletion deduction is computed as a percentage of gross income. So long as operators have enough net income from the property unit, as defined for tax purposes, so that the amount they may take in percentage depletion is not restricted by the fact that it may not exceed 50 per cent of net, percentage depletion in effect makes each added dollar of revenue worth something like 14.3 cents more than it would otherwise be (this being the tax saving, at a 52 per cent rate, on the 27½ per cent of gross revenue it permits to be charged against taxable income). The allowance thus has the same effect as a 14.3 per cent negative excise: an added \$3.00 of revenue from an additional barrel of production becomes worth something like \$3.43.

<sup>17</sup> See n. 16, above. Although these wells are supposed to be defined in terms of the

2. The value of the percentage depletion subsidy is limited to 50 per cent of net income from the property unit. This restriction is most stringent for marginal operations.<sup>18</sup> In consequence, the effect of withdrawing the allowance is likely to be considerably less than is suggested by the \$3.43 to \$3.00 price reduction.

3. Production of the far more important wells subject to prorationing is so restricted by state authorities that they undoubtedly operate far short of the point of rising marginal cost and of its intersection with their individual marginal revenue curves. There is no reason, therefore, why withdrawal of the subsidy would automatically curtail their supply. On the other hand, there is no reason to believe it would expand it appreciably either, and certainly not in such a way as to move the total industry supply curve to the right.<sup>19</sup>

---

marginality of their operations, classification in practice runs principally in terms of the low volume of their daily production, and whether or not they are on the pump [57, pp. 73-75, 322, 329]. Neither of these criteria necessarily means imminent shutdown in the event of any given decline in price. On the fuzziness of their alleged marginality, see [9, p. 235]. Uren cites studies of production costs in 1931-34 showing operating costs averaging 48 cents, 41 cents, and 41 cents a barrel, respectively, for so-called stripper wells in the Mid-Continent and Gulf Coast area producing under 3, 6, and 12 b/d; the posted December low prices for 36° Mid-Continent crude in these four years were \$0.77, \$0.69, \$1.00, and \$1.00, respectively. Other estimates which he cites suggest that a price increase of 20 per cent in 1945 would, by extending the economic life of strippers, have added only 1½ per cent, a 40 per cent price increase 6 per cent, a 60 per cent increase 9 per cent to total recoverable national reserves [55, pp. 24 and 499] [60, Centennial Edition, 1959, p. 374].

<sup>18</sup> [17, p. 1462, n. 61]. To the extent operators can combine properties for tax purposes, in particular grouping some that have relatively large net income with others that have relatively high gross, they can and do mitigate this limitation and come closer to taking the full 27½ per cent deduction. It was to prevent this practice that the President proposed, and the House Ways and Means Committee agreed, to require producers to compute their allowable depletion on a lease-by-lease basis. According to the Treasury, most small operators (who operate most of the stripper wells) compute their depletion in this manner already [*Wall Street Journal*, June 18, 1963, p. 4; Aug. 6, 1963, p. 3] [52, pp. 18, 110-12].

<sup>19</sup> Suppose one were to envisage prorationing as in effect organizing the generally lower-cost wells, whose output alone is limited, as a single, profit-maximizing unit, subject to the limitation that the uncontrolled, higher-cost stripper wells will always be produced up to the point where their marginal cost equals price. The presence of the stripper fringe would hold price lower than the single-firm monopoly level: the demand curve for the flush wells would have greater elasticity than the total industry demand because a lower price would cut out some of the marginal, uncontrolled production. The latter tendency would be the greater, the farther to the right (i.e., the larger the market share at any given price) the supply curve of the marginal producers. Withdrawal of the depletion allowance (under the Davidson assumptions) would raise that curve by 14.3 per cent. Thus the effect of eliminating some marginal production, if any, would be to *raise* the profit-maximizing price for the controlled wells; their output would thus increase by less than stripper production had declined.

Of course, in fact, the nature and motivations of the state regulatory authorities can not be so simply characterized.

4. To the extent stripper output declines, it is not at all clear the states would obligingly permit expanded output from flowing wells sufficient to keep prices from rising. On the contrary, withdrawal of the depletion allowance would provide an excellent occasion and pretext for letting prices go up. Such a price increase, it need hardly be emphasized, would not be the automatic consequence of market forces, competitive or otherwise; with supply subject to stringent control, this sort of short-run reaction could occur only as an act of policy.

The upshot of these considerations is that the burden of withdrawal of the percentage depletion privilege could very well be subject to short-run forward shifting. As Richard A. Musgrave has pointed out, a rise in the corporation income tax could signal a price increase by a monopolist or an imperfectly collusive oligopoly, where the price previously achievable did not maximize industry profit [35, pp. 280-82]. Investment target pretax rates of return in these industries might thereafter be correspondingly adjusted to sustain—even in the face of an inelastic supply of capital in the economy at large—the higher pretax margins required for shifting, provided price remained below the entry-precluding level. So in oil, except that, given the large number of sellers and relative ease of entry, the process would have to be somewhat different. There is a sufficient element of administrative discretion in the pricing of crude oil—where changes in posted prices by major buyers are influenced among other considerations by trends in cost and effectuated or preserved by production cutbacks [9, Ch. 8]—to permit upward adjustment to changes in income tax rates. Once this short-run shifting of a reduced depletion allowance occurred, there would be neither danger of its reversal nor need for its support by longer-run processes, since after-tax rates of return would have merely been restored to their previous level. We return to a consideration of the implications of this possibility below.

It is less clear that the depletion allowance itself or its increased value since 1940, in a world of rising income tax rates, could have been shifted forward (in reduced prices) by such short-run processes. The principal effect has been, rather, to stimulate investment (and increase rents); any tendency it may have had to hold down prices would have been principally long- and intermediate-run in character.<sup>20</sup> We turn therefore to the question of whether the rate of investment it has encouraged has been the appropriate one.

<sup>20</sup> The short-run costs of production, even for secondary recovery operations, are preponderantly fixed [9, pp. 67-68]. At that point however where additional investment is required to sustain the rate of flow from reservoirs already discovered and producing, a point being reached almost daily in one place or other, reduction in the effective price of oil would have an effect. Percentage depletion surely shifts these intermediate- as well as long-run supply curves outward.

### III. *The Issue of Allocational Neutrality*

The major objection offered by economists to percentage depletion (to continue use of this shorthand reference to the whole tax package) is that it results in a misallocation of resources. Since it is the rate of return after tax (net of any required provision for risk) that tends, given free entry, to be equated at the margin between various investment outlets, whereas it is the rate of return before tax that approximates the marginal product of capital, these preferences, which tax net income much less heavily in oil than in other industries,<sup>21</sup> must produce an excessive flow of capital into oil [15, pp. 227-29] [21] [22] [46]. The fact that net returns on investment *after* tax in the oil industry may not be unusually high<sup>22</sup> thus constitutes not a defense of the allowance but the clearest possible proof of the misallocation it causes.

An extremely interesting answer to this criticism has been presented (first, to my knowledge) by Richard J. Gonzalez [18, pp. 993-94], then more thoroughly formulated and tested by McDonald [28] [30], based on the fact that the corporation income tax is itself not neutral in its allocational effects. To the extent that tax is shifted forward, it produces a disproportionately great increase in the price, hence a disproportionate discouragement to utilization, of products where (corporate) profits are high in relation to sales.<sup>23</sup> The latter condition, the argument runs, will prevail particularly in industries—like oil—with two characteristics: a low rate of capital turnover and a high normal return on investment because of above-average risk. Therefore, the depletion allowance, which is in effect a flat percentage reduction in tax in relation to sales, tends to offset or correct the misallocation produced by the corporate income tax's bulking large relative to sales in oil.<sup>24</sup>

The McDonald argument was subjected to challenging criticism by Musgrave [34] and Douglas H. Eldridge [14], to which he in turn re-

<sup>21</sup> McDonald points out that the respective ratios of federal income tax to net before-tax income were 14 per cent and 50 per cent in 1958 [30, p. 370].

<sup>22</sup> This is a matter of dispute. Interestingly, sometimes this alleged fact and sometimes the very opposite one are both cited in defense of the depletion allowance, the first in answer to criticisms that the preferences permit excessive profits, the second in support of the view that risks in oil are unusually great and justify some special tax concession. See, e.g., [18, pp. 994, 998-99].

<sup>23</sup> If the corporate tax rate were 50 per cent, full forward shifting would entail price increases by the ratio of profits to sales: industry A, with a price of \$1 and profits of \$0.05 per unit before imposition of the tax, would succeed in raising its price to \$1.05; industry B, with a price originally at \$1 and unit profits of \$0.20, would have its price raised to \$1.20.

<sup>24</sup> In his original article [28], McDonald made an ingenious set of estimates of these two effects, which seemed to show that the one roughly offsets the other. Subsequent consideration, and a comment by Eldridge [14, p. 215], led him to modify this arithmetic conclusion [29, p. 325].

sponded [29]. The discussion here attempts to summarize the conclusions to be drawn from those discussions as a prelude to taking into account, as they did not, the industry's cartelization.

#### A. *Is the Corporation Income Tax Shifted?*

First, Musgrave pointed out, the argument unrealistically assumes that the corporation income tax is wholly shifted forward (but cf. his later findings [24]). In fact, full forward shifting is necessary to the validity only of McDonald's arithmetic demonstration of *how large* a depletion allowance is required to offset the differential impact of the corporation income tax. Musgrave would apparently not deny that some shifting occurs—to the extent (a) the aggregate supply of savings or its flow into investment is responsive to the net rate of return (compare [20, pp. 216, 235-36] and [35, pp. 278-79, 333] [34, p. 208]); (b) the aggregate supply of savings is diminished because of the disproportionate burden of the tax on incomes (corporate and personal) a high proportion of which tends to be saved [13 pp. 231-32] [43, pp. 224-25]; (c) capital can shift between the corporate and noncorporate sectors; (d) there is short-run shifting, as we have already surmised could well occur.<sup>25</sup> The upshot would seem to be that McDonald's observation remains conceptually sound but is possibly subject to some quantitative discount.

A related qualification, pointed out by McDonald himself, is the possibility that the burden of the tax, and the offsetting benefits of the depletion allowance, are to some extent shifted backward to recipients of economic rent. The more this is so, as we have seen, the less the tax raises price, hence distorts resource allocation, and the less purpose the allowance serves as an offset. We have already alluded to McDonald's judgment that this qualification is not of great importance; and we have offered some indirect evidence to the contrary. In any event, the possibility of backward shifting is relevant only to the quantitative importance of the argument, not to its principle. Backward shifting of the initial burden to rentiers occurs only because the margin is retracted from its optimum point. The fact that a return to that optimum may principally restore economic rents and only slightly increase production capacity (if the slope in qualities of oil-bearing lands is steep) or only slightly reduce price (if supply, as defined, is inelastic, or demand elastic) does not destroy the case *on allocational grounds* for returning.

Of course, the Pareto optimum is not the only proper criterion of public policy. It is relevant to consider, additionally, how high a price

<sup>25</sup> The Musgrave-McDonald exchange does not consider the last possibility at all, further illustrating the initial point of this paper, that the "public finance" literature has given inadequate consideration to the peculiar institutional characteristics of this industry.

in the application of scarce resources to less-promising prospects by marginal operators and in unearned increment has to be paid for the results achieved (compare [11, pp. 412-15] and [26, pp. 255-62]). The economist might still prefer the allocational optimum, accompanied by heavy taxes on the rents. But the rents in oil are not only not taxed away but, *mirabile dictu*, themselves enjoy the tax benefits of percentage depletion!<sup>28</sup>

What *does* strike at the principle of the McDonald exposition, and not merely at its quantitative importance, is the possibility that the demand for the industry's products is relatively inelastic, as he himself avers. The more this is so relative to other industries, the less a relative increase in the price of oil and gas, consequent on the forward shifting of the corporation income tax, necessarily implies *anything* with respect to its allocational neutrality. By the same token, however, the allegedly misallocating effect of the depletion allowance itself would equally be exaggerated. This observation is closely linked with the major thesis of the present paper: If this industry were purely competitive, as most discussions of its tax privileges implicitly assume, the allocational impact of these arrangements would, in my judgment, be of relatively minor importance. It is the industry's cartelization that makes them particularly objectionable, as we shall see.

### B. Profits and Risks in Oil

A second set of questions centers on whether returns on investment in oil are really above average; whether, if so, they represent a necessary reward for unusual risk; and whether the risk-premium component of return on sales, if any, need in fact be reflected in a correspondingly above-average increase in the price of oil even if the corporation income tax is fully shifted forward.

On the last point, Musgrave states that since an income tax with perfect loss-offsets reduces risk, "the tax imposed on the component of profits which constitutes return for risk need not be recouped by higher price . . ." [34, p. 206]. McDonald takes as the measure of the industry's required minimum rate of return (in the presence or absence of an income tax) after-tax profits as observed in the period 1949-56. Then, on the assumption that the tax was in fact shifted forward, he is able to estimate by how much the price of oil would, in the absence of percentage depletion, have been increased more than the price of other products in order to restore the observed higher profit rate. But if in

<sup>28</sup> See [30, pp. 375-76, 380] [37, p. 514], both in opposition. It is difficult to find a convincing defense. See [3]. It should be pointed out, however, that these bonuses and royalties do in fact go to the government, where public lands (including the tidelands and outer continental shelf) are involved.

fact imposition of the corporation tax with loss-offsets had reduced the required return, the price of oil would actually have risen less than this computation would show and perhaps no more than the price in other industries.

The theoretical literature concerning the effect of the corporate income tax with its actually limited loss-offsets on risk-taking investment is inconclusive (see [35, pp. 312-26] [29, pp. 319-21]). But it does appear the McDonald reasoning must be severely qualified. As Eldridge points out [14, p. 212], the unusually great dispersion of results of an individual investment expenditure in oil exploration does not inevitably necessitate a higher-than-average return on total investment in the industry. If this dispersion is the measure of risk, there may be an actual preference for the riskier of two investments promising the same average probable return, when total losses are limited to the funds actually invested and possible gains are virtually limitless: the average return on total investment in parimutuel betting is known in advance to be negative. Moreover, the industry has developed a great number and variety of institutions for minimizing risk [33, pp. 392-401]. (See also [23].)

In any event, the impact on the flow of capital into oil relative to other endeavors of the corporation income tax, on the one hand, and of percentage depletion, expensing of intangibles, and the capital gains option, on the other, cannot possibly be regarded as simply offsetting, either qualitatively or quantitatively. The one operates negatively only to the extent the total flow of capital into corporate investment is in fact responsive to its reduced yield, and demand for oil and gas together is elastic; and it probably operates positively by making the government a 50-50 partner in losses.<sup>27</sup> The other provisions have a complex pattern of effects, all of them positive. Even without percentage depletion, they cause losses to be shared by the government to the extent of 52 per cent (so far as corporations alone are concerned), gains to the extent of only 25 to 52 per cent. Moreover, percentage depletion drastically cuts down the 52 per cent maximum and skews the curve of possible returns far to the right. I hazard the strong impression that the comparative impact of the latter tax provisions on investment in oil

<sup>27</sup> The J. Keith Butters, Lawrence E. Thompson, and Lynn L. Bollinger study found that this last consideration was a relatively unimportant one for most investors. The preponderant effect of the personal income tax was to drive them into lower-yield, less-risky investments. However, they found an equally marked, opposite tendency for those investors interested mainly in capital appreciation; high income tax rates and the differential treatment of capital gains clearly drove most of them into investments offering the greatest opportunity for such appreciation, oil being one of those prominently mentioned [5, pp. 34-43]. I am indebted to my colleague, Robert W. Kilpatrick, for these observations.

far exceeds the inhibiting effect (if any) of the corporate income tax, by virtue of its unequal incidence on industries of above-average risk and capital intensity (see also [47]).

The foregoing discussion, following the literature on the subject, is framed in terms of long-run processes only, and under the implicit assumption of pure competition. In fact, however, these processes and their consequences are significantly altered by the actual institutional characteristics of this industry. What if, then, in the absence of percentage depletion, price-posting by vertically integrated, oligopsonistic buyers, fortified by state production controls, could actually have succeeded in the late 1940's in effecting—and during the 1950's in preserving—a short-run forward shift of the higher corporation income tax rates,<sup>28</sup> as we have already suggested could well occur if the depletion allowance were reduced now? In that event, McDonald's argument about the potential impact of the tax on the oil price could have been right, though for the wrong reasons.

But does the possibility of a rise in the price of oil, effected in *this* manner, constitute an equally compelling defense of the industry's tax privileges on allocational grounds? Given relative ease of entry, the net effect of the corporation income tax, shifted forward in this manner, in the face of a relatively inelastic demand, could well have been an absolutely *increased* flow of capital into oil. This would be so if the total supply of capital to corporate enterprise were inelastic and, as I surmise was the case, most other industries were either less successful than oil in short-term shifting or had higher barriers to entry. The higher price could still have been—as in fact price increases were—preserved in the face of this enhanced investment by equivalent curtailment of production allowables and the imposition of import quotas. In these circumstances, the tax preferences would have *compounded* the misallocation, rather than *corrected* it.

The significance of these observations will be clarified in the ensuing discussion of the third major aspect of McDonald's exposition, the low capital turnover in oil.

### *C. Capital Turnover in Oil and the Influence of Cartelization*

One consideration may be fairly quickly dismissed, having in effect already been resolved: The "capital," though measured on the right

<sup>28</sup> The price increases of 1946-48 would probably have occurred in a purely competitive industry as well; and greater increases could have eventuated automatically if productive capacity were smaller, as it would have been in the absence of the depletion allowance. The real contribution of cartelization was to effect additional, more modest increases in 1953 and 1957, and—probably even more important, quantitatively—to keep the progressively growing excess capacity of the 1950's from wiping out the earlier gains [9, Ch. 8].

side of the balance sheet, reflects inclusion on the left side of investment in leaseholds, valued at acquisition costs. Is it appropriate to include those economic rents, which are price-determined rather than price-determining, in ascertaining the industry's required marginal rate of return on sales? The answer is that the rents paid for superior land are merely the equivalent and consequence of higher nonrent costs at the margin. If the *average* capital turnover figure is therefore reduced relative to the *marginal* by the former's inclusion of lease acquisition costs, this is so only to the extent that it is higher than the latter with respect to other costs. The necessity of earning a return on capitalized rental payments for superior land is a reflection of the process of equating marginal costs and benefits.

A more serious question concerns the implications of the heavy and growing excess productive capacity with which the industry has been saddled since the early 1950's. One evidence of this is the progressive and drastic reduction in the number of days' production permitted controlled wells in Texas, which has borne the brunt of output restriction [9, pp. 156-63] [62, pp. 19-23]—from an average of 345 days in 1947-48 to 97 in 1962.<sup>29</sup> A comparison of the authoritative capacity estimates of the National Petroleum Council with average annual production figures charts the growth of this excess: from 1.0 million barrels a day in 1950-51 to 3.8 million in 1959-60.<sup>30</sup> As Table 1 indicates, production ran around 84 per cent of capacity in the early 1950's<sup>31</sup> then declined steadily to around 64 per cent at the end of the decade. We will consider the cause of this phenomenon at a later point; let us

<sup>29</sup> The annual figures are as follows:

1947	324 days	1951	276	1955	194	1959	123
1948	366	1952	261	1956	190	1960	104
1949	238	1953	236	1957	171	1961	101
1950	230	1954	194	1958	122	1962	97

Sources: *Second Report of the Attorney General* pursuant to Section 2 of the Joint Resolution of July 28, 1955, Consenting to an Interstate Compact to Conserve Oil and Gas, Sept. 1, 1957, p. 86; [62, May 15, 1963, p. 24]; The Railroad Commission of Texas, *Annual Report* of the Oil and Gas Division, 1960, p. 11. Texas' share in national proved reserves shows no decline over these years, while its share of national output has fallen sharply.

<sup>30</sup> The Independent Petroleum Association of America publishes annual estimates of production capacity (see [60]) running slightly lower than those of the NPC, evidently because the IPAA's estimate is of production that could be sustained for 6 to 12 months without further development. Its figure for 1/1/60 is 9,708,000 b/d, which yields an output to capacity figure in 1960 of 69.8 per cent, corresponding to the 64 per cent shown in the table. The trends are similar to those shown in the table, with output in the 1960-62 period continuing to run at just about 70 per cent of capacity.

<sup>31</sup> Actually, as the changing number of days of permitted production in Texas suggest, the 1950-51 average conceals a drop in 1949-50 and recovery in 1951-52.

TABLE 1—U.S. CRUDE OIL PRODUCTIVE CAPACITY, PROVED RESERVES, AND PRODUCTION

	1/1/51	1/1/53	7/1/54	1/1/57	1/1/60
<u>Productive capacity</u>					
(1) (000 b/d) <u>on annual basis</u>	6,727	7,465	8,331	9,867	10,585
(2) (000,000 bbls.) <u>Average production<sup>a</sup></u>	2,455	2,725	3,041	3,601	3,864
(3) (000 b/d)	5,696	6,250	6,184	6,992	6,778
(4) <u>Excess capacity (1-3)</u> (000 b/d)	1,031	1,215	2,147	2,875	3,807
<u>Production as % of capacity</u>					
(5) (3/1)	84.7	83.7	74.2	70.9	64.0
<u>Proved reserves</u>					
(6) (000,000 bbls.) <u>Annual productive capacity</u>	25,268	27,961	29,253 <sup>b</sup>	30,435	31,719
(7) <u>as % of reserves</u>	9.7	9.7	10.4	11.8	12.2

<sup>a</sup> Except for 1954, these are averages for the two years surrounding the date for which the capacity estimate is provided. The first figure, for example, is the 1950-51 average. The 1954 figure is for that single year.

<sup>b</sup> Average of beginning and end-of-year estimates.

assume as proved for the moment (though it is an oversimplification) that it is the consequence of production controls—the familiar outcome of cartelization in an industry where entry is easy.

The burden of this excess capacity reduces the industry's capital turnover. If, despite this, the return on *investment* remains adequate, the industry's rate of return on *sales*—hence McDonald's assumed distorting effect of the corporation income tax and the depletion allowance required to offset it—is unnecessarily inflated.<sup>32</sup>

Does this mounting excess capacity weaken the case for percentage depletion—or strengthen it? In a sense, as McDonald's arithmetic demonstrates, it strengthens it. If we must take production control as given, we must also accept the cost of the excess capacity it imposes. The tax privileges keep investors contented with a price lower than it would otherwise have to be. The industry's rapidly mounting excess capacity, which was certainly attributable in part to the enhanced real value of the tax preferences after World War II, in a context of higher general income tax rates, probably did make it more difficult to raise prices as unit costs seemed to mount and profit margins to decline in the 1950's: the power of the cartel over price was not unlimited; cut-backs in Texas were partially offset by expanding output in states not

<sup>32</sup> This idea was first suggested to me by my graduate student, Dane J. Cox.

practicing similar restraint and by rising imports. From this perspective, then—taking production control as an unalterable fact of life—one might well argue on allocational grounds for an allowance even more generous than it would otherwise have to be, in order to offset the price-boosting effect of the cartel.

But this view makes sense only to the extent that the subsidy does indeed affect quantities produced and consumed. The economic purpose served by increasing the flow of capital into an industry is to reduce the price and promote the utilization of its products. The allocational case for the depletion allowance is, thus, seriously weakened when a large proportion of the capacity thus created is merely shut in and prices are prevented from falling. While the tax allowance is tending, through its effect on investment, to reduce price relative to cost, production control thwarts that tendency and pushes up costs relative to price. When the higher costs, to which the subsidies themselves contribute, are then proffered in partial justification of those same subsidies, the argument completes the circle, and it becomes reasonable to ask whether it may not be time to break out.<sup>38</sup> Before attempting to

<sup>38</sup> The depletion controversy provides numerous intriguing illustrations of the principle of self-justifying irrationality—the tendency for irrational interferences with the free market to produce results which are then cited in justification of the original interventions. For example, reference is frequently made, in defense of the allowance, to the high and allegedly rising costs and risks of exploration. Yet the offer of the subsidy to an industry characterized by statically increasing costs is itself in some measure responsible for extending the margin of cultivation, raising real costs (including risks taken) at the margin, and rents within the margin. See, e.g., [37, p. 509].

Again, Gonzales defends the 27½ per cent rate on the ground that it usually produces tax savings less than those of cost-based depletion, so far as purchasers of proved oil properties are concerned. Oil in the ground sells for \$1 a barrel or more; this could be charged off on a cost basis, whereas, at a market price of \$3, percentage depletion would come at most to only \$0.825 [18, pp. 996-97]. What this ignores is that the \$1-a-barrel price is not independent of percentage depletion. For one thing, the availability of that option to the *seller* is an important determinant of his reservation price—a fact which Gonzales in effect concedes when he points out, in another defense of the 27½ per cent, that finders of oil are constantly weighing the alternative benefits of operating the properties themselves, and enjoying the 27½ per cent deduction, or selling out for capital gains: “any reduction of percentage depletion would swing the balance more heavily in favor of sales of reserves in the ground” [18, p. 997]. Moreover, the price buyers are willing to pay is itself a function of the cost of finding oil on their own account, and this, too, we have just pointed out, is influenced by the subsidy.

Another argument frequently encountered is that the importance of cheap fuel for economic growth justifies retaining these special inducements. The argument is often made but never rigorously developed. All sorts of possible applications of resources might contribute importantly to growth; there remains the inescapable problem of choosing among them. Until parents are permitted to expense such intangibles as their children's tuition costs, and to charge off depletion—even on a cost basis—for investment in education, it is an open question whether the particular subsidy to the consumption of gasoline by college students in sports cars is on balance justified.

A final illustration—perhaps better characterized in this context as the principle that one irrationality deserves another—is the argument that one cannot condemn the alloca-

answer, however, we will have to consider whether that circle may not also be encompassing national interests other than optimal resource allocation.

#### IV. *Excess Capacity, Cartelization, and National Security*

From time to time the view has been attributed to military authorities that national security requires we keep some one to two million barrels a day of production capacity in reserve for national emergencies. The goal, it should be noted, is capacity that is not just excessive, by ordinary economic standards, but also unutilized. (Industries like agriculture, bituminous coal, and textiles have been periodically or chronically plagued by excess capacity; but one of their main difficulties has been an inability to keep the excess *idle*. See, e.g., [42, pp. 736-39].) This view in effect constitutes a strong defense of the very combination of institutions here under examination.

It is production control, not the depletion allowance, that is principally responsible for the oil industry's holding its excess capacity idle. Certainly it would not remain idle if we were to return to the law of capture, either without restriction or within the limits of maximum efficient rates of production (MER). And if we adopted the only rational system of organization—unit operation of reservoirs—excess capacity of the kind that our present, irrational method of exploitation fosters would not come into being in the first place, the subsequent discussion will more fully show.<sup>34</sup>

---

tional consequences of the depletion allowance without also considering the heavy taxes that directly and indirectly discourage the consumption of gasoline. See, e.g. [18, pp. 999-1000]. A survey of the relevant data and literature leaves the strong impression that we can not yet say with assurance whether the motorist is overtaxed, and perhaps we never will. Does a verdict of unproved for the entire package then vindicate percentage depletion? In principle, yes—partly. But, first of all, taxes on one final product, even the most important one, can never correctly offset or be offset by subsidies on the raw material. Second, as a practical matter, it seems intolerable to have to decide about everything before deciding about anything. The rule that one alleged wrong deserves another can lead to a stagnation of policy-making. Finally, if our argument is correct, that the depletion allowance leads more to an accumulation of idle capacity than to lower prices and enhanced utilization, the subsidy could not in any event offset the allocational effects of overtaxing the motorist. The two problems can therefore be confronted separately.

<sup>34</sup> The present system of production control is certainly far superior to the preceding one, competitive exploitation *under the law of capture*. But it is important to understand wherein the improvement lay, and that is the reason for emphasizing the qualifying phrase. The critical flaw is not always explicitly identified; the impression is therefore sometimes left that competition itself is inherently infeasible in oil.

Competition *as a force in the market* does not require that every individual worker be "in business for himself" *within* the individual producing establishment. On the contrary, it assumes a centralized control based on property rights coterminous with the integrated unit of production. So in the case of oil: compulsory unitization, by eliminating the insanity of competitive exploitation of the individual reservoir, would, as Davidson

This conclusion requires some qualification: the tax privileges are not entirely blameless for the industry's system of control, the wide gap it maintains between price and costs of efficient production, and hence for both the excess capacity and its enforced idleness. Percentage depletion creates an artificial incentive on the part of vertically integrated refiners to take their profits at the production end of the business, hence probably makes them more ardent supporters than they would otherwise be of the cartel-sustained price of crude oil.<sup>35</sup> The large purchasers

shows, make it possible for each physical establishment to be run rationally while escaping the severe defects of prorationing to market demand. See also [32, pp. 110-21] [55, pp. 175-83, 572]. There has been no demonstration that competition in the market place would not then perform its social role of coordinating the behavior of these individual, profit-maximizing units. See [9, Ch. 10] [44, Ch. 6], a pioneering discussion. Cf. [1, pp. 55-58].

What of the alleged threat of destructive competition in the presence of heavy fixed costs in oil? In pointing out that depreciation and depletion are typically charged on a unit-of-production basis—i.e., only as each barrel of oil or mcf of gas is produced—rather than automatically with the passage of time, de Chazeau and I were concerned to deprecate this alleged danger, observing that, in the absence of a rule of capture, market competition would be subject to the ability of each (unitized) producer to withhold from producing today what he feels might be more valuable tomorrow [9, p. 72, n. 23 and pp. 71-72, 239, n. 17, 243]. We erred at one point, as Davidson shows [7, pp. 87-88, n. 5], in characterizing depreciation and depletion on this account as variable in the economic sense, rather than fixed—i.e., in confusing these book charges with user costs. The capital outlays these accounting entries seek to recoup are indeed sunk, and these charges *as such* do not enter into the decision whether or not to produce. What does however remain valid is the basic point that the low ratio of variable to total *production* costs would not in itself make competition destructive, absent the rule of capture; that, given unitization, it would be only if market price covered also (discounted) marginal user costs that production would actually be undertaken and the book depreciation and depletion charges be actually recorded. See [7, pp. 91-94, 97-98].

<sup>35</sup> See [33, p. 155] [9, pp. 221-29] [7, pp. 98-100] [27, pp. 102-6]; also [2, pp. 106-18], supplying additional reasons for the major companies' interest in a high and stable price of crude oil.

McDonald has challenged the relevancy of this motivation: given the freedom of entry into production, he avers, "it is a motivation without power" [29, p. 317, n. 18]. The principal answers, I believe, are the following: (1) Until the imposition of import quotas, in 1959, the world oil price was tied to the U.S.; conditions of entry and independence of action in foreign oil falling far short of effectively competitive, a rigged U.S. price therefore meant greater monopoly profits than otherwise for the international companies. (2) Free entry tends to bring down to "normal" levels the profits of the "representative producer." It does not eradicate the supernormal returns of the successful operators, and specifically of the "representative majors." The discrepancy in profitability between successful and unsuccessful firms is probably unusually great in this business. See, e.g., the comparative profits of firms showing net income and of all reporting firms in [14, p. 215]. On the enduring advantages of large producers, see [31, pp. 550-51, 556-57]. This is another way of saying that entry is not really so utterly free in oil as is suggested by the fact that new ventures are constantly being formed—attracted in large measure by the tax arrangements that make it possible for investments to be privately successful even when total outlays exceed total receipts (see [37, p. 510] [22, pp. 18-19]). A high price that induces a lot of wildcatters to drill dry holes will mean higher profits than a lower price for the big company that has tied up the more promising acreage and con-

of oil, who post the field price, are typically reported as arguing on balance on the side of more stringent cutbacks of production allowables at the monthly meetings of the Texas Railroad Commission;<sup>86</sup> and this pressure does in fact amount to a call for a higher price, hence (given an inelastic demand) a greater stimulus to investment relative to the permitted level of production than if the market were more competitively organized. But clearly the price policies of the integrated companies would be far less effective in the absence of prorationing and import quotas; to these government controls must be attributed the principal responsibility.

Apart then from its possible contribution to the organization and functioning of the cartel, the depletion allowance does not itself encourage holding discovered oil in reserve. On the contrary, its benefits come only as the oil is actually produced.<sup>87</sup> The contribution of the tax privileges to the alleged national security goal, rather, is to make it possible for investors to tolerate, and by their continued investment to maintain, a larger capacity, idle or otherwise, at any given price, than they otherwise could or would.

---

trols the wet holes. (3) Even if a rigged price could not guarantee supernormal profits, the major refiners might still prefer a higher price *cum* excess capacity to a lower with less crude-oil-producing capacity, in view of their long-run interest in continuity and adequacy of supplies. Meanwhile they can and do exert their influence to induce state authorities to curtail by direct, well-spacing regulation the kinds of competitive entry and development most costly to them. (4) To the extent supernormal profits in production are eroded away by secret concessions from posted prices, possibly reflected in turn in product price reductions, the integrated company can still enjoy the tax advantage of transferring crude oil to the refining department at the posted price, taking its nominal profits at the production end.

At the same time, McDonald's observation (which he has most helpfully elaborated in private correspondence) constitutes a useful reminder of what the majors have doubtless been discovering for themselves: that they cannot raise prices indefinitely without attracting entry and forcing costly production cutbacks on themselves. This discovery corroborates the consideration raised in n. 19, above: that the presence and possible entry of independents increase the elasticity of demand and reduce the profit-maximizing price of the owners of low-cost wells. The major companies could escape this burden and increase their monopoly profits so long as they could produce abroad and bring in low-cost foreign oil without restriction under the U.S. price umbrella. But this door too has now been partly closed, and the foreign price level cut loose by import quotas from the domestic. In the circumstances, Paul H. Frankel raises the interesting question "to what extent is proration as we know it now still as acceptable to the biggest companies, as it undoubtedly was 30 years ago?" [16, p. 67].

<sup>86</sup> See the monthly reports of these meetings in the *Wall Street Journal*.

<sup>87</sup> See [37, pp. 510-11] [19, pp. 433-34]. Nelson suggests that the stimulus imparted by percentage depletion is almost entirely to development rather than exploration. I do not follow his reasoning. True, the producer reaps no tax benefits until production commences; but it is equally true of all investment and regardless of the tax system that profits wait upon revenue. Whatever increases the prospective flow of net revenues after tax surely encourages both longer- and shorter-term expenditures to expand output.

But what precisely is the nature of this excess capacity that has grown so sharply since 1950-51? The table in note 29 and Table 1, above, suggest that it has certain peculiar characteristics. It is apparently *not* an excess of proved reserves: the ratio of proved reserves to annual production (the so-called Life Index) has shown no trend whatever since World War II.<sup>38</sup> Thus "production capacity" seems to have increased steadily relative to proved reserves—from 9.7 per cent at the outset of 1951 to 12.2 per cent nine years later, as the table shows, and higher since then.<sup>39</sup>

In short, the excess capacity of recent years apparently consists entirely of an ability to take out of the ground more rapidly than before oil that has already been discovered.<sup>40</sup> This trend is the consequence of many factors, including improved well-completion and secondary recovery techniques. But one prominent factor has been intensive developmental drilling of known or already discovered reservoirs. Actually, developmental drilling did not increase relative to exploratory over the entire postwar period. Under the influence of various short-term stimuli—the enhanced value of the tax preferences because of sharply rising income tax rates, the rapidly growing demand for oil and

<sup>38</sup> The average of the annual ratios in the 1955-62 period was slightly over 12.4 years; for 1946-54, it was not quite 12.5 (computations from [61], comparing yearly production with end-of-year reserves). In 1951, for example, when allowables were 276 days and output at some 90 per cent of capacity, the Life Index was at 12.4 years; in 1962, when controlled wells in Texas were permitted a puny 97 days, and excess capacity nationally was estimated at 3.5 to 4 million b/d (and output averaged 7 million), it was 12.3.

<sup>39</sup> The IPAA production capacity estimates (see n. 30, above) were 11.2, 11.4, 11.6 and 11.8 per cent of proved reserves at the outset of 1960, 1961, 1962, and 1963, respectively.

<sup>40</sup> The foregoing statistics understate the extent to which this is so. Estimates of proved reserves are recomputed annually (and typically upward) as a result of two processes: new discoveries, consequent on exploration, estimated as proved at the end of the year of discovery; and revisions and extensions (typically positive) of previously estimated discoveries, principally as developmental drilling demonstrates how much was in fact discovered in preceding years.

Extensions and revisions have accounted for by far the greater proportion of total additions to proved reserves and have showed some tendency to increase in relative importance since World War II: 82.7 per cent of the total in 1946-50, 84.3 per cent in 1951-56, 86.8 per cent in 1957-62. These in turn represent an increase over the previous decade: the ratios were 78.6 per cent in 1937-40 and 80.0 per cent in 1941-45. Computations from [61].

Thus the development of known reservoirs has been reflected not only in growing estimated productive capacity but also in growing estimates of proved reserves, via revisions and extensions. So in the ratios shown above, rising from 9.7 to 12.2 per cent, developmental drilling has been increasing the denominator (via extensions and revisions) as well as the numerator, hence underestimating the extent to which we have merely been more intensively cultivating and exploiting fields already discovered rather than finding new ones.

gas, and general anticipations of inflation—exploratory drilling increased very sharply during and after World War II relative to the total (see [60, Centennial edition, 1959, pp. 16, 22]). But then, as permitted days of production were sharply curtailed, pay-out periods painfully extended, and the burden of excess capacity mounted, it was exploratory drilling that was disproportionately discouraged: the number of wildcats drilled in 1962 was 31 per cent while all other (primarily developmental) well completions were only 18 per cent below their respective 1956 peaks.<sup>41</sup> Over the entire period, development of known reservoirs, including secondary recovery, has tended to gain relative to new discovery.<sup>42</sup>

The economic explanation of these respective trends in exploration and development seems to lie in two sets of causes. The first, a combination of market imperfections with aspects of the cobweb and acceleration phenomena, is fairly obvious: the lead time between the commencement of exploratory activity and of production typically involving several years, exploration overresponded both to the enhanced incentives of 1940-53 and—in the opposite direction—to the industry's less buoyant prospects after 1956.

The second cause was prorationing. A cartel that, by controlling production, holds price far above the short- and long-run marginal costs of the more efficient producers but does not effectively restrict entry will inevitably produce overinvestment. The burden of this waste falls differentially on exploratory as against developmental drilling. For the explorer its only effect is to promise a long-delayed pay-out if he does in fact strike oil: the cutbacks in output fall mainly on the lower-cost and generally the newer wells. For the individual producer sitting atop a known reservoir, in contrast, the drilling of another developmental well promises an almost certain (only one in four to one in five development wells proves to be dry) additional ticket of admission to the cartel; it guarantees an additional quota, at the rigged price, hence the

<sup>41</sup> Calculated from data reported in the *Annual Review-Forecast* issues of *The Oil and Gas Journal* (late in January of each year).

<sup>42</sup> See also n. 40, above. Further evidence of the same trend has been the sharp and continuous increase in the relative importance of stripper and secondary recovery production, from 15.2 to 22.3 per cent of the national total between 1951 and 1960—a trend only partially explained by the progressive cutbacks of allowables on more productive wells. See [48, p. 18].

Again, between the 1950-51 average and 1961, production from other than stripper wells rose 15.8 per cent, nonstripper proved reserves 22.1 per cent, and the number of producing nonstripper wells by no less than 33.2 per cent. These divergencies in trend appeared entirely after 1955-56. All computations, from [60] and [48], were made by subtracting the stripper data (using only "primary" stripper reserves) from the national totals. I am indebted to Herman Roseman for helping me work out the logic of this comparison.

possibility of a faster pay-out. So it pays a leaseholder on proved properties to drill more wells than he would in the absence of production controls or if reservoirs were unitized.<sup>43</sup> The exemption of secondary recovery operations from production control has the same effect. For all producers as a group the process is of course self-defeating—additional wells and quotas merely necessitate additional cutbacks of allowables; but no one of them can afford to hold back. The result, since developmental drilling (and secondary recovery) increases the potential recovery rate, and since marginal, high-cost wells that would otherwise be forced to close down are exempt from output limitations and sheltered by the rigged price, is to widen the margin of idle capacity.

The tax laws, too, in a sense discriminate against exploratory and in favor of developmental activity. The costs of drilling and equipping wells, most of which can be charged currently against income, constitute the major part of developmental outlays. On the other hand, a large proportion of exploratory costs—notably the outlays for geological and geophysical work and lease acquisition—must be capitalized and amortized, so long as the leases in question are not abandoned. Industry spokesmen have pointed out this anomaly, urging that the expensing privilege be more fully extended to exploratory outlays as well [25, pp. 1019-21]. The foregoing discussion suggests the advisability of reversing the discrimination. The various defenses of these special tax arrangements for oil—notably risk and low capital turnover—apply, if they apply at all, principally to exploration. The “intangible” drilling costs of developmental wells, in contrast, are really the costs of acquiring a perfectly tangible asset; how risky they really are is suggested by the widespread recourse to three- to ten-year bank loans to finance them (see, e.g., [49]); and their contribution to national productive capacity consists essentially in making it possible, at wastefully excessive cost, to take known reserves out of the ground at a more rapid rate for a relatively short time [9, pp. 160, 232-33] [36, pp. 27-28].

So our reserve productive capacity is a short-term phenomenon. The more enduring measure of capacity is proved reserves, and these not only show no rise relative to production but have (because of rising imports) declined relative to consumption since World War II. Industry spokesmen point to these facts as demonstrating that the incentives conferred by the depletion allowance ought in no way to be dimin-

<sup>43</sup> See [32, pp. 110-21] [9, pp. 236-39] [33, pp. 111-12, 381-82] [16, pp. 86-90]. Also the testimony of William J. Murray, then Chairman of the Texas Railroad Commission, in U.S. House of Representatives, Select Comm. on Small Business, *Small Business Problems Created by Petroleum Imports*, Nov. 1961, p. 113.

This is not to minimize the progress made recently by both Louisiana and Texas toward improved well-spacing regulation and giving increased weight to acreage in assigning allowables. An enormous encouragement to overdrilling remains. See [59] [10].

ished;<sup>44</sup> it would be entirely consistent with their logic and these facts to argue for making the tax incentives even more generous.

Before contemplating this piling of irrationality on irrationality, we should consider whether the case may not have been overproved. The so-called Life Index was 12.7 years in the 1920's, 13.8 in the 1930's, and 12.5 in 1946-62, with no trend apparent in the latter period (computations from [60] and [61]). Of all the oil that is underground, the amount actually "proved" at any given time is only a fraction; it is far from a full reflection even of all the oil that has already been discovered and will prove to be recoverable even with currently available techniques, let alone the far greater supplies—from oil reservoirs discovered and as yet undiscovered, from the vast oil shales and tar sands—that future technological progress and growing demand will make it economical to produce [39, pp. 7-63]. It is expensive and wasteful to do the drilling to prove out in advance more reserves than are needed as a kind of on-the-shelf inventory (see [38, tr. pp. 6336-47]). If the industry has tended, decade in and decade out, to keep an inventory about 12½ times current sales, it is questionable whether it even can, let alone ought to, be induced to hold more.

The mere fact that we can open the valves in case of national emergency and increase the flow of oil for a period of time measured in years, without any need to increase drilling, certainly must in a sense contribute to national security. But this fact cannot be appraised in isolation. The 10,585,000 b/d we could produce at the outset of 1960 were more than we could refine: total refinery capacity, some of it obsolete and inoperable, was only 9,800,000 b/d on that date [51]. Other surface facilities for storing, handling, and transporting the oil similarly did not match our ability to produce it [36, p. 5]. For all-out nuclear war the reserve is surely useless. For a longer war of attrition, the question must be posed and answered whether this is the kind of reserve we want or whether instead we may not prefer to have more oil discovered and requiring only development.<sup>45</sup> Or, to what extent, alter-

<sup>44</sup> See, e.g., *The Petroleum Situation*, Chase Manhattan Bank, April 1963, p. 3. Their argument provides another instance of self-justifying irrationality. Noting that the ratio of proved reserves to production has been roughly constant over the decades, Gonzalez asserts: "One of the best reasons for maintaining percentage depletion at existing rates is that the system has worked to encourage development of new resources at about the rate required to meet the needs of our expanding economy" [18, p. 998].

The subsidies encourage *both* exploration and production. That the two have grown roughly *pari passu*—in general, the more we produce the more we look for and find—is no indication that the rate of growth of both and their absolute levels today are the economically desirable ones.

<sup>45</sup> Jerome J. O'Brien, Director of the Department of Interior's Office of Oil and Gas, calls for a 70 per cent (7,000 wells) increase in exploratory drilling, "to maintain our reserves," "paralleled by a reduction of at least 7,000 unnecessary development wells" [40, p. 5].

natively, compressible normal civilian consumption might not serve as our principal reserve.

The choice among these and other alternatives cannot be made intelligently without considering their respective costs; and the costs of the present policies are immense. Industry representatives estimate that on the order of \$500,000,000 annually are spent drilling unnecessary developmental wells.<sup>46</sup> And this entirely apart from the additional wastes involved in denying ourselves the foreign oil that can be delivered on the East Coast at a cost \$1.25 to \$1.30 a barrel less than domestically produced crude—total output of which was over 2.5 billion barrels in 1962.<sup>47</sup> Only in terms of comparative costs can we choose between maintaining the present shut-in capacity and being prepared instead to draw upon another reserve, as yet unmentioned: the possibility of permitting production in excess of MER's, as happened for a time during World War II. It is difficult to believe that the costs of the latter recourse—which would be incurred in the future only if and as necessary and would consist of some sacrifice of ultimate primary recovery—could (appropriately discounted) possibly exceed our equivalent current expenditure on unnecessary wells, which have the principal effect of putting us in a position to use up more rapidly what has already been discovered.

### V. Conclusion

The depletion allowance does sustain real investment in oil exploration and production, though much of its benefit is dissipated in raising economic rents and in the higher real costs of the marginal operations it encourages. But production controls have seriously attenuated the connected between investment and the level of capacity, on the one hand, and the level of output and price, on the other—not surprisingly, since both industry spokesmen and the Texas Railroad Commission regard the demand for oil and gas together as highly inelastic. In these

<sup>46</sup> See M. J. Rathbone, then President of Standard of New Jersey [41, p. 5], Lyon F. Terry, of Lehman Brothers, formerly Vice President of the Chase Manhattan Bank [50, pp. 9-10] [32, p. 116] and n. 43, above.

What is superfluous or unnecessary is seldom rigorously defined in these estimates. But all carry the implication that this is drilling that does not increase ultimate recovery and would not be done if the reservoirs were unitized; hence the expenditures are justified on grounds of neither efficiency nor economy.

It perhaps goes without saying that this waste is not the fault of any individual or firm, but the consequence of a violently irrational industrial organization and control.

<sup>47</sup> It is not suggested that all our needs could be supplied from abroad at such a cost saving or that it would be desirable to do so. On the other hand, the fact that Middle Eastern reserves, already discovered and proved out, are six times ours and are produced at the rate of only about 1 per cent a year while ours are at 8 per cent is suggestive of the extremely high potential elasticity of foreign supply.

circumstances, the incremental investment encouraged by the depletion allowance has taken the form largely of idle short-term production capacity; the allowance makes investors willing and able to carry a larger cost burden of this kind than they otherwise could or would. Its withdrawal, by reducing after-tax rates of return, would curtail investment until the reduced burden of idle capacity had restored returns to their equilibrium level.

What of the possibility that the industry might instead shift its added tax burden forward, as we have concluded it well might, despite its heavy excess capacity? If it did so, the price we are paying for the system of production controls and the system of import limitations that reinforces it would be no greater than before; it would merely be clear for all to see, instead of concealed by the tax subsidy. Perhaps this development would increase the likelihood of a more rational public policy along these fronts as well. Absent such reform, the excess capacity would remain, its burden carried more by the consumer and less by the general taxpayer.

The question then is whether the excess capacity is nonetheless worth having in the interest of national security and worth its cost. It would be an amazing historical coincidence if it were. The complex of regulations and incentives surrounding this industry could not by the remotest stretch of the imagination be described as having been evolved in accordance with some prior military determination; and of course the cost is not incorporated in the defense budget.<sup>48</sup>

These costs are of an entirely different character, as well as order of magnitude, from those of any misallocations of resources to which percentage depletion might (or, following McDonald, might not) give rise in a purely competitive situation. In such a context, the net loss would merely be the difference in the contribution to consumer satisfaction from marginal bundles of inputs applied to oil and gas rather than to other goods and services. But in the context of cartelization, most if not all of the additional short-term production capacity that the tax allowances encourage investors to bring into being is both unused and, except for the claimed contribution to national security, unnecessary; the marginal social product of the investment is zero.

It would seem difficult for an economist to justify the retention of arrangements that conflict so violently—I think most disinterested observers would agree—with common notions of equity and make investors willing to commit so egregious a waste of resources.

<sup>48</sup> "If there is one thing clear about our domestic crude oil policy, it is that it has never been frankly explained to the citizens who pay the price, nor fully debated by the Congress that has enacted, piecemeal, the legislation under which production is restrained, imports restricted, and exploration tax-subsidized" [12, p. 299].

## QUANTITATIVE ANALYSIS OF THE COLLECTIVE FARM MARKET

By JERZY F. KARCZ\*

In the course of the campaign to eliminate private trade in the USSR during the early stages of rapid industrialization, an effort was made to channel the entire marketable surplus of farm products through state distribution outlets. These proved unable to handle the task with the means placed at their disposal, and the continuing pressure of rising demand upon declining output resulted in the emergence of a *de jure* black market. Faced with this situation, the Soviet leadership found it convenient in 1932 to resurrect the ancient, and but recently and officially discarded, institution of the so-called bazaar trade (or farmers' markets). These markets were re-established under a new name and subjected to strict government controls [25]. Ever since, the collective farm market (hereafter briefly referred to as "the market") has continued to function as the only market in the otherwise tightly planned economy where prices are established by the interplay of demand and supply.

During the last decade, the importance of the market in the Soviet distribution system has declined, but its position as a source of urban food supplies is still very respectable. According to an official statistical handbook, it accounted for 14.1 per cent of "sales of comparable food products" in 1961 [30, p. 632]. All averages, however, can be made to cover a variety of sins, and it appears that this one is no exception. Around 1960-61, the share of the market in "total sales to population" was said to exceed 50 per cent for a number of products [1, p. 54]. In 1957, when the corresponding handbook percentage was 18.2, the share of the market in total physical volume of sales to population was 63 per cent for potatoes, 48 per cent for eggs, 35 per cent for vegetables, and 23 per cent for meat products [6, p. 15].<sup>1</sup>

\*The author is assistant professor of economics at the University of California, Santa Barbara. He is indebted to Nancy Nimitz and Gregory Grossman for useful comments and to the Inter-University Committee on Travel Grants, the American Council of Learned Societies, and the University of California for financial assistance. James J. Sullivan and Robert P. Anderson helped with the calculations.

<sup>1</sup>In 1957, the share of the market in all purchases by families of those employed in industry was: 28 per cent for meat, 26 per cent for fresh milk, 54 per cent for eggs, 67 per cent for potatoes, and 39 per cent for vegetables [21, p. 8].

Collective farm market continues to provide a substantial proportion of total money income of the agricultural population, especially in the collective farm sector. Given our present state of knowledge on this subject, it is not possible to obtain the exact share of market sales in this income, but some impression of its importance may be gained from the following figures. In 1957, total distributions by collective farms as labor day payments to their own members have been estimated at 41-48 billion (old) rubles [16, p. 276] [17, p. 318], while market sales by collective farm members (including rather insignificant sales by other Soviet citizens who also trade on the market) were 40.5 billion rubles [6, p. 89].

The knowledge of quantities of various farm products marketed through collective farm market, as well as of prices prevailing in such transactions, is essential to Western analysts for many purposes, including the estimation of national income accounts, calculation of average farm prices, construction of food balance sheets, and the like. Unfortunately, data of this sort have not been published recently. Under the circumstances, specialists on the Soviet economy (including the writer) have been forced to make their own estimates, based *inter alia* on official Soviet price and quantity indices for the total "extra-village collective farm market trade" (to be defined presently). The validity of these estimates, however, has been beclouded by uncertainty as to the coverage of some underlying Soviet data as well as by some confusion as to the relationship of collective farm market prices to either state retail prices or to prices realized in the so-called commission trade.<sup>2</sup>

It is the purpose of this article to discuss the nature of market statistics with the aim of clarifying some of the issues of their interpretation and to present a series of estimates of "extra-village" market prices as well as of quantities sold on this market during the years 1940, 1950-62. My estimates are based partly on information provided by a rather inaccessible but obviously very well-informed source [6] and in part on the official data of the Central Statistical Administration. Except for a few rather insignificant departures, the estimates obtained are consistent with the official Soviet indices referred to above. For reasons of space, the description of methods has been reduced to a minimum; details are set forth in a mimeographed appendix obtainable from the writer on request.

<sup>2</sup> The term "commission trade" describes sales on the market through the intermediary of cooperatives who collected a commission from 1953 through 1960. In 1961, this trade was replaced in part by the urban trade of the cooperatives, who now buy from producers at local market prices and sell at the market prices ruling in the city where the sale to the consumer takes place.

The article deals exclusively with the Soviet collective farm market, but it is believed that many of the problems discussed here are also relevant for the study of similar "farmers' markets" which survive in other countries of the Sino-Soviet bloc. Since marketing without middlemen also plays a substantial role in underdeveloped countries generally, the issues raised by the Soviet experience would seem to have an even wider applicability.

## I

### A. Terminology

The term "collective farm market trade" (*kollektivnaya torgovlia*) has been used in the USSR to describe a variety of economic phenomena.<sup>3</sup> The most inclusive definition of this trade refers to all sales of farm products (including sugar) by collective farms and their members to buyers other than state procurement agencies. This definition covers, therefore, not only sales at market-determined prices (or prices agreed upon by buyers and sellers) within or without the agricultural sector, but also sales of farm products, at prices controlled by the state, to institutions other than state procurement agencies. A more restrictive concept eliminates sales to institutions (known also as decentralized procurements) but still includes the "intra-rural" turnover or sales within the agricultural sector. Another definition covers the so-called "extra-village collective farm market," defined in official sources as "sales of farm products by collective farms, collective farmers and other individuals who own a subsidiary farm plot to non-agricultural population and to institutions at prices determined on the market" [28, p. 708]. This concept, to which the published Soviet indices as well as the official data on the value of sales refer, includes therefore sales to rural but nonagricultural population. There are, however, even more restrictive definitions of "collective farm market trade." The term has been used on occasions to refer to urban trade only, to sales within markets of 251 cities where basic statistical information is collected, or to even smaller samples of 101 or 71 large cities.

Unfortunately, Soviet economists have never been exposed in a systematic fashion to Professor Fritz Machlup's strictures on pitfalls resulting from confusing use of terminology. Generally speaking, they use the term "collective farm market" very loosely. Thus, although

<sup>3</sup> For a more complete discussion of this aspect see [7, pp. 97-101] and [10, Appendix C]. Dr. Naum Jasny seems to imply that differences in definitions might partly be accounted for by the use of different Russian terms, such as "markets" instead of "market." This might well be true at times. But many Soviet economists use the various Russian terms interchangeably [1, p. 44] and this appears to be the more general practice.

the late Professor M. M. Lifits (who had also served as the deputy minister of trade for the USSR) once spoke explicitly of "urban collective farm markets" [13, p. 285-86], a closer examination of the evidence made it clear that he was actually describing developments on markets of the 251 sample cities alone [31, p. 185].<sup>4</sup>

### B. *Soviet Data on the Market*

It will be useful to begin with a brief description of Soviet data-collecting methods, as this will enable us better to appreciate the reliability of the various Soviet figures. Fortunately, a fairly full description of these processes has just been published by an outstanding authority on the subject [1].<sup>5</sup>

For reasons that will become clear immediately, Soviet authorities are unable to determine the quantities sold on the market (however defined) or prices ruling in market transaction through enumeration. Market sales take place in the USSR on some eight thousand urban and rural markets set aside for this purpose by local authorities. Many transactions that would fall within the scope of extra-village market sales take place outside the boundaries of these markets, either through home delivery, through street sales (nominally illegal), or through other informal arrangements [10, pp. 131-32] [22, p. 32].

Data on the volume of market sales of 72 products are gathered daily on all markets located in 251 Soviet cities by enumerators employed by market administrations. In addition to sight estimates, the enumerators (whose professional and educational qualifications have been described as "not high, as a rule" [1, p. 29]) also utilize information provided by the would-be seller at the time of his entry on the territory of the market [1, p. 26].

Price information is gathered by personnel of state statistical agencies for 73 products (including sugar distributed to farmers involved directly in beet production at discount prices) on the 25th day of each month *only*, and for the most part only on the main market(s) of each of the 251 sample cities. In addition, price registration for 17 products takes place on the Sunday closest to the 25th day of the month on markets located in all *raion* centers (county seats), which may or may not be classified as urban. An attempt is made to register actual (as

<sup>4</sup>In [8, p. 449] Dr. Naum Jasny assumes that "every statement of the market trade pertaining to the present and the past [refers] to the total trade as *now* [italics in original] officially defined as ex[tra] village trade, unless the opposite is definitely obvious from the source." It would have been far better to conclude that such an assumption is permissible only if it is supported by the sources explicitly.

<sup>5</sup>I. K. Beliaevskii wrote a dissertation to satisfy requirements for the *kandidat* degree in economics on this subject, as well as several other articles. As his recent book includes all the material needed here, reference is made to [1] only in order to economize space.

opposed to "bid" or "ask") prices at the time of the most active trade. In all cases, the prices registered are to refer to first-grade products only (and this is said to lead later to "some overstatement of the value of trade turnover") [1, pp. 18, 26-28].

With two exceptions (potatoes and vegetables during the summer months), price quotations obtained in this fashion are converted into average monthly prices by means of unweighted averaging of prices registered during the current and the preceding month. Thus, the June price is taken to be the unweighted average of quotations for May 25 and June 25. In further calculations, though, average monthly prices are weighted by quantities sold. Some difficulties arise in the calculation of the average price for a territorial unit, such as a republic. Since no quantity data are collected in the *raion* centers, the average republic price is derived as an unweighted average of prices collected on all of its markets [1, pp. 57-58].

The sample of 251 cities referred to above is far from representative. This has been made clear by the results of a general survey conducted during the week of April 10-16, 1957 on 3,888 markets of 2,813 cities and 1,809 markets of 1,787 rural *raion* centers. The sample cities include 58.1 per cent of total population of cities and urban settlements and, during the week referred to, accounted for 61.2 per cent of the total value of trade (defined presumably in this instance as trade on markets of surveyed and sample cities taken together) [1, pp. 37, 47]. But the percentage of urban population accounted for by towns of less than 10,000 inhabitants in the 251 sample cities is only 0.1 per cent, whereas the corresponding percentage in the universe is 8.7 per cent. The corresponding figures for cities of 10,000-20,000 and 20,000-50,000 inhabitants are, respectively: 0.5 and 10.3 per cent; 4.3 and 15.6 per cent [1, p. 30]. As a result, the sample of 251 cities cannot be described as truly stratified. In the words of the leading Soviet authority on market statistics [1, p. 37]:

... one can agree that the existing [data collecting] procedures aim at the description of collective farm market trade in large cities. But the question then arises: why does [the sample] include a very insignificant number of smaller cities? Data collected there cannot be representative and do not exert a significant influence on averages and relative indicators of the sample.

Such, briefly, is the basic raw material gathered by Soviet authorities for the purpose of calculating price and quantity data on the market. As the reader will have noticed, the information obtained leaves much to be desired as to representativeness though not neces-

sarily as to comparability.<sup>6</sup> Among the outstanding shortcomings are: lack of quantity data for the *raion* centers (where price data are gathered), the practice of obtaining prices for first-grade products only, and the use of unweighted averages for the purpose of calculating average monthly prices. In all fairness to Soviet statistical agencies, it should be added here that the nature of the observed phenomena does not render their task a smooth and easy one, even though the first shortcoming could easily be remedied without much additional expenditure of real resources.

### C. Soviet Estimating Procedures

Our understanding of data on the extra-village market, published annually in official statistical handbooks, would be vastly improved if the information on procedures used in the compilation of the series were made freely available. Regrettably, this is not the case. We have known for some time which index-number formulas are used in the calculation of price and quantity indices,<sup>7</sup> and we know what procedures are used in the aggregation of data collected in 251 sample cities. It is also known that the Central Statistical Administration makes no calculations describing the urban (as opposed to the extra-village) market trade. But Soviet sources are silent on the exact methods of generalizing on the basis of the sample.

Strictly speaking, this remains an unanswered question. But two Soviet sources [1, p. 44] [19, pp. 32-33] provide enough clues to conclude that, in addition to data on trade in sample cities, the statistical agencies make substantial use of information provided by annual reports of collective farms and those institutions which purchase farm products on the markets as such [33, pp. 63-64] or directly from producers at market-determined, or mutually agreeable, prices. Furthermore, data derived from sample budgets of collective farmers as well as those of workers and employees are employed extensively in this connection.

The reliability of these data leaves much to be desired. The sample of workers' budgets was described in 1957 as "not sufficiently representative of urban population" generally [23, p. 31]. Until 1959, no

<sup>6</sup> Except insofar as the size of the sample changed over time. During the 'thirties, price information was gathered at ten-day intervals rather than once a month, as is the case today.

<sup>7</sup> The justification for the use of the Paasche formula for price indices may be of interest. According to [1, p. 73] this is "inherently" superior to the Laspeyres formula in this context as it immediately reveals the "savings" realized by Soviet population as a result of price declines. As far as the collective farm market is concerned the argument is obviously fallacious. Needless to say, it was advanced before the increase in state retail prices of meat (30 per cent) and butter (25 per cent) [26].

sample budgets were collected from agricultural families other than those of collective farmers, and sales by such families were assumed to take place at rates determined from budgets of collective farmers [19, p. 33]. We cannot be sure that financial reports of institutions buying on the market are fully reliable, as these may show a bias towards underreporting, especially with respect to prices. Finally, corrections are also made (we do not know upon what basis) for sales taking place outside of the territory of the markets.

Under the circumstances, one statement can be made with confidence: with the exception of data referring to 251 sample cities, the volume data on extra-village market sales are Soviet estimates, the reliability of which varies inversely with the increase in scope of collective farm market trade.<sup>8</sup> The information on prices obviously falls into the same category but, for reasons already noted, its reliability is even more questionable. In spite of all this, however, various Soviet official data represent the best information that is available to us on this important subject, even though one is tempted occasionally to classify it somewhat facetiously among the "best Soviet informed guesses."

#### *D. Conclusions on Price Comparisons*

The foregoing description also throws some light on the important relationship of state retail to collective farm market prices. Beliaevskii states that one of the reasons why first-grade-product prices are collected is the desire to preserve reliability and comparability of quotations over time [1, p. 18]. In stating emphatically that the comparisons of state retail to collective farm market prices are limited to 101 largest cities (all of which form a part of the larger sample of 251), he also implies that comparisons of this sort are made for first-grade products only. Until and including 1960, such comparisons were published regularly in official statistical handbooks, e.g., [29, p. 718], but others were also made by various Soviet economists who, to my knowledge, are never sufficiently explicit about the nature of the comparison or the coverage of the underlying data. On the other hand, we know that Soviet statisticians, when calculating indices of real wages, shy away from the calculation of average retail prices, i.e., averages of state retail, cooperative trade, and collective farm market prices. The explanation given is "the difficulty due to the complexity of determining 'average purchase prices' for any one product" [4, p. 194]. It would follow that it is equally difficult to compare average state retail prices to average collective farm market prices for the

<sup>8</sup> We cannot, however, be sure that data which describe extra-village turnover only are more reliable than those which include the "intra-rural" turnover as well.

USSR as a whole, and that such comparisons are not made as a matter of statistical routine. Hence, it must be assumed that all such comparisons refer to prices of first-grade products only and that they are limited to a sample of 101 or, perhaps at times, 251 cities. It then follows that any effort to draw generalized inferences about the relationship of state retail to collective farm market prices (as is done, e.g., in [2]) must necessarily assume that trends in prices for first-quality products are representative of trends in average prices for the same products and, furthermore, that whatever is true of the limited (or otherwise undefined) sample is also true of the USSR as a whole. The first assumption appears to be quite plausible at first glance but need not always turn out to be so. The second, however, is definitely untrue. As we already know, even the larger sample of 251 cities is not adequately representative of collective farm market trade, defined in any way but that of trade in the same 251 cities. This conclusion was reached by some Soviet economists even before the April, 1957 survey of most urban collective farm markets [20, p. 10-11]. Thus, those who wish to draw such inferences must necessarily proceed at their own peril.

## II

### A. *Methodology*

Efforts to estimate the volume of extra-village market sales are inextricably linked with the problem of determining the composition of market output of the various farm products. Market output, or marketings, is defined officially as including "farm products delivered and sold to the state, to co-operatives, and also sold on the market to non-agricultural population" [29, p. 883]. The last category, therefore, is identical with the definition of extra-village market sales.

The composition of market output has been described recently as follows [12, p. 160]: (i) state procurement; (ii) collective farm market sales to nonagricultural population and institutions (i.e., extra-village turnover); (iii) decentralized procurement, or direct purchases from producers by agencies involved in retail or wholesale trade and catering; (iv) deliveries of institutional farms to their parent organizations; and (v) distribution of farm products by collective farms to hired but basically nonagricultural labor as partial payment in kind.<sup>9</sup>

<sup>9</sup> [12, p. 160] also lists the following components of market output: distribution of farm products in kind to state and institutional farm workers and allocation of farm products by state and collective farms to their own canteens. While such ways of disposing of the product are included in the definition of market output which includes "intra-village" turnover, they cannot be included in the officially published data defined to exclude sales or distributions to agricultural population.

Of all the foregoing, data are available only on the volume of marketings and state procurement. The latter are stated partly in terms of physical and partly in terms of the so-called accounting weight, i.e., grain of standard moisture content, etc.<sup>10</sup> It follows that by subtracting from the total volume of marketings the sum of state procurement and estimated market trade, one obtains a residual which ought to be large enough to cover reasonable estimates of items (iii) through (v) above, as well as the difference between the physical and the accounting weight of state procurement, whenever applicable. My estimates of the volume of extra-village market sales proceed in accordance with this criterion.

The procedures employed in this study can be summarized as follows (a full description is given in the Appendix): the basic source for the estimates [6, p. 15] shows data on the percentage breakdown of value of extra-village market trade in 1950 and 1957 for seven major product groups. This information is said to be based on materials of the Central Statistical Administration. Since the total value of this trade is known for both years, ruble data for each of these product groups can be determined easily.

For 1957, the same source [6, p. 87] also shows the percentage of commission trade in the total volume of extra-village market trade (including commission sales) for six of the seven product groups. Since the volume of commission sales for 1957 is known or can be estimated within a small margin of error [28, p. 653], the volume of total market trade can easily be obtained for the main six product groups. Prices ruling in the extra-village trade in 1957 can be calculated by dividing value by volume data. Substituting the 1957 price and quantity figures into the appropriate Soviet indices of extra-village market trade for each of these six product groups, I obtain data shown in Table 1. These serve henceforth as my estimates of the relevant magnitudes.

### *B. The Estimates*

The estimates are internally consistent with other Soviet evidence, provided by source [6] or by official indices and discussed further in the Appendix. As a further check, price and quantity indices, using formulas applied in such computations in the USSR, have been calculated with the aid of data shown in Table 1. The six major product groups for which I show estimates accounted for 79 per cent of the total value of extra-village trade in 1950; the corresponding figure for 1957, including commission sales, is 78 per cent. On a priori

<sup>10</sup> On this vexing subject, see [9].

TABLE 1—ESTIMATED VOLUME OF SALES AND PRICES, EXTRA-VILLAGE COLLECTIVE FARM MARKET,<sup>a</sup>  
SELECTED PRODUCT GROUPS, USSR, 1940, 1950-62

Product Group	1940	1950	1951	1952	1953	1954	1955	1956	1957	1958	1959	1960	1961	1962
A. Quantities Sold (Million tons or billion eggs)														
1. Grains	0.81	3.29	3.91	4.28	3.85	2.75	2.33	2.85	2.77	2.52	2.40	2.19	1.86	1.67
2. Potatoes	2.19	6.46	6.13	6.20	6.26	6.50	6.53	6.62	6.32	6.46	6.31	5.69	5.72	5.26
3. Vegetables	1.49	1.56	1.61	1.73	1.97	1.95	1.94	1.83	1.83	1.98	1.65	1.58	1.39	1.42
4. Milk <sup>b</sup>	2.09	2.42	2.36	2.40	2.47	2.43	2.86	2.51	2.26	2.07	1.94	1.86	1.76	1.84
5. Meat+Fat	0.69	0.79	0.67	0.69	0.73	0.77	0.78	0.81	0.84	0.82	0.75	0.69	0.83	0.98
6. Eggs	1.20	1.37	1.73	2.33	2.80	3.08	3.14	2.86	3.03	3.06	3.11	3.17	3.14	3.20
B. Prices <sup>c</sup> (new rubles per ton or thousand eggs)														
1. Grains	250	330	300	270	240	280	290	230	230	230	200	210	230	230
2. Potatoes	140	110	120	140	130	160	150	130	110	140	130	140	140	160
3. Vegetables	150	190	250	210	200	200	180	150	180	190	220	180	200	210
4. Milk <sup>b</sup>	250	230	240	250	240	280	270	250	220	230	240	240	270	280
5. Meat+Fat	1,430	1,330	1,450	1,560	1,430	1,500	1,590	1,400	1,420	1,460	1,370	1,470	1,630	1,730
6. Eggs	102	106	101	104	97	103	100	101	100	104	103	105	107	113

<sup>a</sup> Including commission trade.

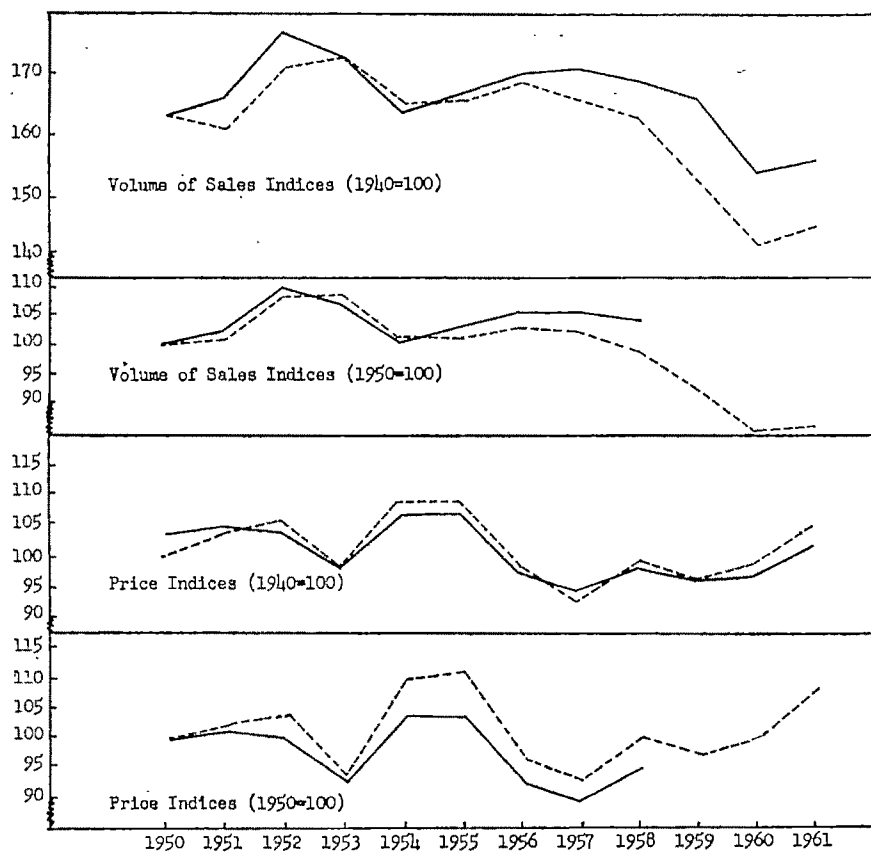

<sup>b</sup> Including milk products in terms of milk equivalent.

<sup>c</sup> Prices have been rounded to the nearest 10 rubles per ton or one ruble per thousand eggs. Unrounded prices in terms of old rubles are shown in the sources.

Sources: Appendix Tables I through VI.

grounds, therefore, one expects a reasonably close correspondence between the indices so computed and the official Soviet indices for the total extra-village market. Comparisons of this sort are presented in Chart 1. As will be seen there, my price indices move reasonably close to the official Soviet indices, so that no additional comment is called for here. This is also true of the quantity index based on 1950 = 100.

CHART 1. OFFICIAL AND CALCULATED INDICES OF EXTRA-VILLAGE  
COLLECTIVE FARM MARKET, USSR

Note: ——— official indices  
----- calculated indices

Source: Appendix Tables XI-XIV.

As for the quantity index based on 1940, the calculated index follows generally the trends of the official index, but beginning with 1956 it does so at a somewhat lower level. The explanation for this behavior must take into account the remoteness of the 1940 base year,

as well as the behavior of the Soviet index for fruit, which is also available in the official handbooks. Fruit forms a significant part of the product groups for which I show no estimates, and which include livestock, mushrooms, honey, sugar, berries, melons and the like. The Soviet fruit index, which generally moves at a lower level than the index for all sales until 1954, begins to show much greater increases in the years 1955, 1958-59. This helps to account for the discrepancy referred to above. In 1960 and 1961, however, the fruit index shows very pronounced declines, which should bring the Soviet index closer to my calculated index. This does not occur and the explanation must be sought partly in the remoteness of the base year and partly in the possible trends for other omitted product groups.

Data presented in Chart 1 offer, I believe, additional confidence in the estimates presented in Table 1. Errors due to conversion and rounding are not believed to exceed 5 per cent.

### III

Our remaining task is that of evaluating the estimates in the light of information provided by other Soviet sources which might be used in the making of similar estimates as well as to deal with some objections that might be raised by one or more *advocati diaboli*.

#### A. Evaluation of Volume Estimates

As far as the order of magnitude is concerned, my volume estimates for 1950, 1954, and 1958 are consistent with partial information provided by two independent Soviet sources [3, p. 50] [5, pp. 236-37]. On the other hand, my estimates for 1956 and 1957 are not in agreement with statements made by two other Soviet sources [14, pp. 120-1] [27, p. 7]. None of the latter, however, defines the term "collective farm market trade" with any degree of precision, nor is the source of their data stated explicitly. By contrast, my estimates refer uniformly to the concept of extra-village market and are based on information which is ultimately homogeneous with respect to its source (Central Statistical Administration). Consequently, I see no reason for concern over this incongruity.

On the other hand, the very order of magnitude of my volume estimates might be considered to be excessively high. Those who might be tempted to reason in this fashion would do so presumably on the basis of information provided for the 251 sample cities in the official handbooks.<sup>11</sup> The unrepresentativeness of this sample, especially with respect to the concept of the extra-village market trade, has already been commented upon. My high estimates essentially mean that the

<sup>11</sup> See Appendix, Table X.

market plays a much less significant role in supplying the population of larger cities with purchased foodstuffs than it does in providing them for inhabitants of smaller towns as well as for members of rural but nonagricultural population. This is in agreement with statements of other Soviet sources as well as observations of Western travelers.<sup>12</sup>

Moreover, my high estimates of the volume of market sales fit quite well with data on the share of the market in total "sales to population" (cf. page 315 above). On the other hand, estimates of much lower order of magnitude would have to face a difficult task of reconciling these two sets of data. First, one would be hard put to explain what the state does with the procured output (even though we all agree that there is considerable waste at this stage). Second, low estimates for extra-village market sales open another Pandora's box with respect to the composition of market output, as they would leave uncomfortably large totals for decentralized procurement and deliveries of institutional farms. On all these grounds I consider my estimates to be of the right order of magnitude.

#### *B. Market Prices and Commission Trade Prices*

The reliability of my price estimates remains to be examined. These might first be compared with prices prevailing in the commission trade (and shown in the Appendix, Table XV). Such a comparison reveals a number of instances where my estimated prices are lower than the commission trade prices, especially (though not exclusively) for grains and potatoes. In view of many Soviet statements to the contrary, this might at first glance cast some doubt about the results of my estimates. For a number of important and relevant reasons, however, comparisons of this sort involve substantial pitfalls of interpretation.

To begin with, many if not all of the Soviet statements just referred to are based explicitly or implicitly on official tabulations of prices ruling in the sample of 101 largest cities. This is even less representative of average market prices than the larger sample of 251 cities.

To the extent that such statements do not refer to such samples (I am not aware of a single statement that could not be construed to do so by implication), they must refer to products of the same quality, sold in the same locality (or on the same market) at the same time.

<sup>12</sup> This is evident from statements that prices are much lower in smaller cities as made, e.g., in [1, p. 59] or [15, p. 13]. According to [22, p. 15], the share of the market in total retail sales in the Ukrainian *oblast'* center Poltava (1959 population: 143 thousand) was: 65 per cent for meat, 92 per cent for vegetable oil, 58 per cent for eggs, 11 per cent for fresh milk, 75 per cent for vegetables, and 79 per cent for potatoes. Data refer to 1958.

Otherwise, they lose much if not all of their meaning. Now, there are many reasons to believe that the total commission trade market and the extra-village market (excluding commission sales) are in fact close to being two separate markets, which overlap primarily in larger cities only. To begin with, the improvement of supply of larger cities (through acquisition in relatively inaccessible rural areas) was the main reason for the introduction of the commission trade in 1953, and it is known that this trade often includes interregional shipments.<sup>13</sup> Secondly, commission trade does in fact appear to be concentrated in the larger, though not necessarily the largest, cities, while collective farm market trade proper takes place primarily in the smaller towns.<sup>14</sup> Thirdly, the commission trade is still relatively insignificant compared to the total extra-village trade (cf. Table 1 and Appendix, Table XV).

To the extent that the two markets are, by and large, separate entities, comparisons of prices for the commission trade taken as a whole and the entire extra-village market depend to a very large extent upon the choice of weights. There is first the variation of prices due to the difference in the location of sales between the small and the large city. Second, there is the issue raised by the fact that Table 1 shows estimates for product groups defined rather broadly (e.g., my grain group is composed not only of the different varieties of grains but also of the grain equivalent of all kinds of flour, baked products, as well as groats and legumes). There is no a priori reason to expect that the product mix *within* each product group is the same for the commission trade as for the total extra-village trade (even though the latter includes the former as far as my estimates are concerned). In fact, for some product groups, the difference in product mix may be very pronounced, as the shares of feed grains and fresh milk might be expected to vary inversely with the size of the city where the transaction takes place. Finally, there is the problem raised by the pronounced seasonal variation in collective farm market sales and prices. Since product mixes for the two markets differ, the appropriate seasonal indices might also show pronounced differences.

For all these reasons, therefore, it is to be expected that what might be true of price relationships holding for identical products, sold in the same locality and at the same time, need not at all be true of the

<sup>13</sup> In 1954, potatoes acquired by cooperatives for commission sales in the central black-soil region were shipped for sale to Rostov, Krasnodar, and even to the Turkmen Republic in Central Asia [32].

<sup>14</sup> According to [32] the share of commission trade in total supply of the population of the Estonian capital of Tallin was: 23.4 per cent for potatoes, 46 per cent for vegetables, 8.5 per cent for meat, and 11.5 per cent for fresh milk.

same relationships as far as average prices for the commission trade and the extra-village market are concerned. That this is so might best be illustrated by the following arithmetical example, bearing on only one of the problems discussed above. Assuming that the relevant magnitudes are as shown below (we are comparing, say, milk data for a hypothetical republic), the average collective farm market price of 244.40 rubles per ton is less than the commission trade price of 253.70 rubles per ton, even though individual market prices are uniformly higher than the commission trade prices:

	Extra-village market		Commission trade	
	rubles/ton	% of sales	rubles/ton	% of sales
Large cities	266	40	256	95
Small towns	230	60	210	5

Lest I be misunderstood, I wish to make it clear that a *broad* relationship between average commission trade and average collective farm market prices is to be expected, even though the comparisons are subject to all the pitfalls enumerated earlier. For example, I would be disturbed if the commission trade prices exceeded my corresponding estimates by a factor of 2 or so. Since this is not the case, we need say no more on this account.

### C. Market Prices and State Retail Prices

There remains the problem of the relationship of my estimates to state retail prices. We are told time and time again that collective farm market prices are significantly higher than state retail prices. We have already discussed the fact that general Soviet statements of this sort are based upon limited and unrepresentative samples. But similar facts have also been observed by Western observers (including the writer), and it is obvious that some broad correspondence between my price estimates and state retail prices should also exist, even though much of what has just been said with respect to comparisons involving commission trade prices also applies here.

No Western calculations of average state retail prices for the six product groups for which I present estimates exist at the time of writing. Some data on state retail prices for roughly comparable products are presented in Table 2 for the median retail price zone II as well as for the lowest retail price zone I. As it turns out, my price estimates for extra-village market are generally higher than state retail prices (with a single exception of milk for 1958, where the departure from this rule is not too significant).

This, however, is true of averages. In larger cities, market prices are considerably higher than state retail prices; my estimates are

therefore consistent with the proposition that in many smaller towns market prices are at times below state retail prices. Is this state of affairs theoretically possible, especially in the light of the weighty argument advanced by Professor Nicholas Spulber who concludes: ". . . two prices cannot, however, prevail for the same commodity when the state price is higher [than the market price]. In this case these [state] shops simply price their commodity out of the market" [24, pp. 98-99]?

Strange as it may seem, Spulber's analysis is tacitly based upon assumptions usually associated with the working of perfect com-

petition (complete mobility, perfect knowledge, lack of marketing costs). But he also assumes that state shops *always* have something to sell; otherwise their prices lose much of their leverage effect, although they can still exert some influence on the level of market prices (for example by determining the initial level of asked prices). Quite often, however, state retail shops run out of some foods even in the larger cities,<sup>15</sup> and I already stated my belief that the market provides the bulk of purchased supplies in smaller towns.

The seasonality of agricultural production, combined with the lack of adequate storage facilities in the hands of small producers, results in some very pronounced seasonal variation in supply on the extra-village market. That this is also reflected in pronounced price variations suggests that market prices tend to be affected much more by fluctuations in supply than by those in demand. In terms of the famous analogy, it is the supply blade of the scissors that tends to move more often than the demand blade (cf. also [18, pp. 30-31]). Additional factors, reinforcing this tendency, are to be found in the high transport costs associated with the collective farm market. Once these had been incurred, the seller would ordinarily attempt to spread them over a large volume of sales without paying too much attention to the price towards the end of the day. Taken by themselves, supply factors might be expected to push market prices below the level of (largely fictitious or paper) state retail prices in the smaller town during the periods of peak seasonal trade when much of the turnover materializes.

It is to be expected, of course, that a floor exists below which market prices would not normally decline regardless of the seasonal trends in supply, but it is not easy to determine the exact level at which it would be established. Theoretical considerations point to the level of prices realized by the farmers in state procurement, increased by the amount of marketing costs attributable to a unit of product. In the USSR, or elsewhere for that matter, a peasant farmer cannot always be expected to engage in such a refined calculation, but this need not deprive him of the title of rational man. For clearly some utility may be derived from a trip to town, however small.

Something remains to be said for the demand side. If there are no opportunities to buy at state retail stores, the volume of demand directed at the collective farm market might be expected to be larger, thus nullifying to some extent the influences working on the supply

<sup>15</sup> On March 11, 1962 I observed a collective farm market price of 0.50 rubles/liter in the city of Iaroslavl' (1959 population: 407 thousand). A Soviet citizen queried on the level of state retail price for milk replied: "0.29 rubles/liter, but there isn't any." As it turned out, there was but little milk in one state store that morning.

side. But people who live in smaller Soviet towns rely to a considerable extent on their own household plots for food supplies. While more recent data are lacking, the private nonagricultural household plot accounted for the following percentages of total per capita consumption in the nonagricultural sector in 1956 [11, p. 33]:

Meat	14.1 per cent
Milk	20.3 per cent
Eggs	37.7 per cent
Potatoes	31.1 per cent
Vegetables	18.1 per cent

These are averages for the USSR as a whole; in smaller towns the percentages are likely to be much greater. Under the circumstances, I do not believe that demand shifts can, on the average, outweigh factors acting on the supply side; it is the latter that must exert the dominant influence on prices in smaller cities and hence on much of the total market turnover. Professor Spulber's conclusion appears to be disposed of quite effectively even without recourse to an argument based on market imperfections. Surely, he would be the last to claim that these do not exist in the USSR.

#### IV

In conclusion, it seems advisable to emphasize the major points of the discussion. First, unless a source defines the meaning of the term "collective farm market trade" very precisely, the information so provided should be treated with great circumspection. It is hoped, of course, that the estimates presented here will assist other analysts in the future interpretation of such data. Second, the importance of the market in the total food supply of the nonagricultural population is still quite substantial, especially when reference is to the smaller towns or urban centers. Third, chiefly as a result of weighting problems, comparisons between average market prices for commodities defined rather broadly and similar prices effective in other retail markets in the USSR are not very meaningful at best and may, at times, be quite misleading. Fourth, the level of market prices (especially in the smaller cities) is more often responsive to fluctuations in supply than demand. Fifth, the fact that I have apparently been able to present estimates which are very close to the figures employed for the same purpose by Soviet statistical agencies should not obscure the fact that the very nature of these data leaves much to be desired. Sixth, it should be remembered that my estimates apply to a particular concept of "extra-village collective farm market" (in-

cluding commission trade).<sup>18</sup> Although they might help to reduce the range of speculation about magnitudes appropriate to other definitions of this elusive and so often misinterpreted term, they should not be used indiscriminately.

## AN INTERNATIONAL COMPARISON OF FACTOR COSTS AND FACTOR USE

### *A Review Article*

By WASSILY LEONTIEF\*

For over 30 years—to be exact, since 1928—whenever a working economist was called on to describe in numbers or to interpret in analytical terms the relationship between the inputs of capital and labor and the final product of a plant, an industry, or a national economy as a whole, he was more likely than not to reach out for the Cobb-Douglas production function. Theorists questioned the arbitrariness of its form and statisticians the validity of procedures used in fitting it to given sets of data, but despite all criticism the familiar exponential equation was used over and over again, essentially, I think, because of its convenient simplicity. But now this remarkable career is apparently coming to an end. The old formula is being rapidly replaced by a new, improved recipe: the constant elasticity of substitution production function. In quantitative empirical analysis, the C.E.S. function can perform essentially the same role that the Cobb-Douglas function played up until now, but, owing to its less restrictive shape, it offers at the same time the indisputable advantage of greater flexibility.

In this monograph,<sup>1</sup> the new tool is used with considerable skill in a statistical inquiry designed to test—and, as it turns out, to disprove—one of the factual assumptions of the much-debated Heckscher-Ohlin interpretation of the classical theory of international trade. Mr. Minhas is one of the four joint authors—Professors Arrow, Chenery, and Solow are the others—of the article<sup>2</sup> published three years ago in which the C.E.S. function was not only described in some detail, but also, so far as I know, for the first time fitted to actual statistical data. Thus, it is not surprising to encounter in his book formulations and arguments already developed, or at least suggested, in that article.

The principal ideas are developed in four chapters which make up the first half of the book; the three remaining chapters are devoted to systematic statistical description and international comparison of the rates of return on capital in different industries. Presenting the results of what apparently first was conceived as a separate inquiry, the second half of

\* The author is professor of economics at Harvard University.

<sup>1</sup> Bagicha Singh Minhas, *An International Comparison of Factor Costs and Factor Use*. Contributions to Economic Analysis, No. 31. Amsterdam: North-Holland Publishing Co., 1963. Pp. xii, 124. Paper, \$4.20.

<sup>2</sup> "Capital-Labor Substitution and Economic Efficiency," *Rev. Econ. Stat.*, Aug. 1961, 43, 225-50.

the book bears only a loose, sketchily delineated relationship to the central line of argument developed in the first four chapters.

In a laudable endeavor to bring together theoretical and factual analysis, Minhas continuously shifts his argument from one to the other. For purposes of a critical review it seems to be more appropriate, after restating the substantive issue to which he addresses himself, to examine separately the new tool he chooses to use, the specific method of its application, and the interpretation of the results obtained.

The factual assumption of the modern theory of international trade that Minhas sets out to disprove is that a meaningful distinction can be made between capital- and labor-intensive industries, a distinction that incidentally plays a crucial role in analysis of economic development.

If the amounts of capital and of labor employed per unit of their respective outputs were technologically fixed, the ranking of different industries in accordance with the relative magnitude of the two input coefficients would certainly be valid. It still would be meaningful even if, in response to a given change in relative prices of the two factors, capital were substituted for labor or vice versa, provided the downward or the upward shifts of the capital-labor input ratios were so uniform as not to disturb to any significant extent the relative position of the individual industries on the capital-labor intensity scale. If, on the contrary, some industries responded to a given change in the relative price of the two factors by a much larger shift in their relative inputs than others, then their comparative position on the capital-labor intensity scale would often be reversed. The distinction between capital- and labor-intensive industries must lose in such a case much of its analytical usefulness. Neither in explanation of the pattern of international trade nor in the study of economic growth would it be permissible to utilize it as a technological datum. Minhas sets out to demonstrate empirically that this is actually the case, and he employs the constant elasticity of substitution production function to do so.

The constant elasticity of substitution—or as Minhas prefers to call it, the homohypallagic—production function can be written in the following form:

$$(1) \quad V = (AK^{-\beta} + \alpha L^{-\beta})^{-1/\beta}$$

where  $V$  represents the output;  $K$  and  $L$  stand respectively for the inputs of capital and labor. Each one of the three quantities should be thought of as being measured in different physical units or, in the case of aggregative analysis, described by an appropriate index number.  $A$ ,  $\alpha$ , and  $\beta$  are constants which are supposed to reflect the technical characteristics of the particular production process. If  $K$  and  $L$  on the right-hand side of the formula are multiplied by an arbitrary positive constant,  $\lambda$ , the corresponding total output on the left-hand side will become  $V\lambda$ : this means that the production function described by equation (1) is homogeneous of the first degree; it obeys the law of constant returns to scale.

The partial derivatives of  $V$  in respect to  $L$  and  $K$ , i.e., the marginal productivities of labor and of capital, are:

$$(2a) \quad \frac{\partial V}{\partial L} = \alpha \left( \frac{V}{L} \right)^{\beta+1} \quad (2b) \quad \frac{\partial V}{\partial K} = A \left( \frac{V}{K} \right)^{\beta+1}$$

and the marginal rate of substitution of capital for labor—let it be called  $x$ —is:

$$(3) \quad x = \frac{\partial V}{\partial L} / \frac{\partial V}{\partial K} = \frac{\alpha}{A} \left( \frac{K}{L} \right)^{\beta+1}.$$

Translated into logarithmic terms, that equation describes a straight line:

$$(4) \quad \log x = \log \frac{\alpha}{A} + (\beta + 1) \log \left( \frac{K}{L} \right).$$

Its constant slope  $(\beta+1)$  is the reciprocal of the elasticity of substitution between capital and labor,  $\sigma$ :

$$(5) \quad \sigma = d \log \left( \frac{K}{L} \right) / d \log x = \frac{1}{\beta + 1}.$$

To demonstrate that the Cobb-Douglas production function represents a special case of the C.E.S. function in which  $\sigma=1$ , i.e.,  $\beta=0$ , we can rewrite (3) interpreting its left-hand side as a derivative of  $K$  in respect to  $L$  along a constant output curve:

$$(6) \quad \frac{dK}{dL} = - \frac{\alpha}{A} \frac{K}{L} \quad \text{or} \quad - A \frac{dK}{K} = \alpha \frac{dL}{L}.$$

Integration of the two sides of the second expression gives:

$$(7) \quad V = K^A L^\alpha$$

where the constant of integration,  $V$ , represents the output measured in appropriately defined units. After raising both sides of (1) to the power  $\beta$ , we can see that  $A+\alpha=1$ , if  $\beta=0$ , which is indeed the condition satisfied by the two exponents in the homogeneous Cobb-Douglas production function.

Perfect substitutability between capital and labor can also be interpreted as being a special case of the C.E.S. function (1): If  $\sigma = \infty$  and consequently  $\beta = -1$ , it acquires the simple linear form,

$$(8) \quad V = A\bar{K} + \alpha L.$$

On a familiar two-dimensional graph the corresponding isoquants are represented by a set of negatively sloping parallel straight lines.

At the opposite extreme, when the elasticity of substitution tends toward 0 and  $\beta$  tends toward  $\infty$ , equation (1) degenerates into an input-output relationship characterized by constant capital and labor coefficients of production. However, for reasons that I will explain later, this rather special inter-

pretation of strictly complementary relation between capital and labor, though formally correct, is apt to be misleading when applied in statistical analysis of observed facts.

If a profit-maximizing industry considers the price of labor,  $w$ , and the price of capital,  $r$ , as given, it will employ these two factors of production in such amounts as to equate the price ratio,  $\frac{w}{r}$ , to the marginal rate of substitution of capital for labor. According to (3) and (4), in the case of a C.E.S. function, the dependence of the factor input ratio,  $\frac{K}{L}$ , on the price ratio,  $\frac{w}{r}$ , is described by the simple log-linear relation,

$$(9) \quad \log\left(\frac{w}{r}\right) = \log \frac{\alpha}{A} + (\beta + 1) \log\left(\frac{K}{L}\right).$$

Minhas illustrates his crucial argument concerning the possible effect of changing price ratios on the capital-labor input ratio in different industries by drawing the graph in Figure 1.

The two lines represent the relationship between the capital-labor ratio,  $\frac{K}{L}$ , and the relative price,  $\frac{w}{r}$ , in two different industries. The first industry will be more capital-intensive (and less labor-intensive) than the second if the labor-capital price ratio happens to be higher than  $\frac{\bar{w}}{\bar{r}}$ , but the second

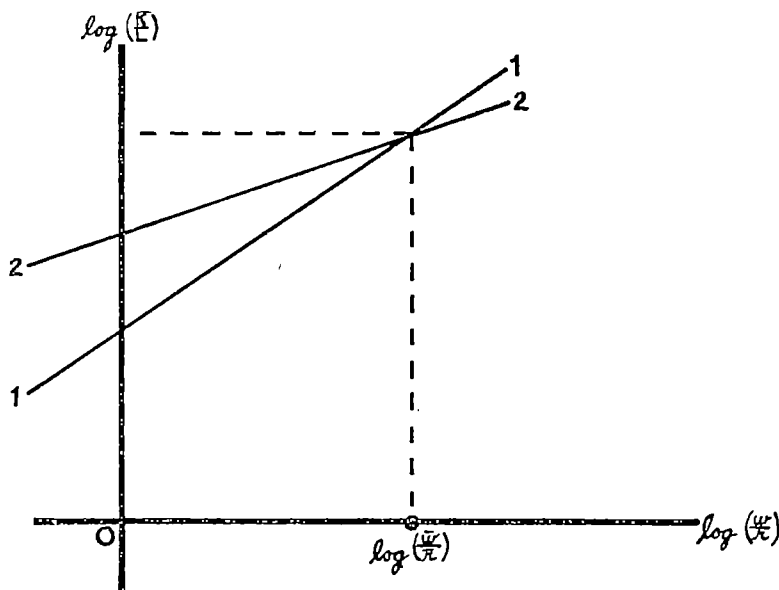

FIGURE 1

will become more capital-intensive (and less labor-intensive) than the first if the labor-capital price ratio is lower than the critical level,  $\frac{\bar{w}}{\bar{r}}$ . The point  $A$  at which the two industries, while confronted with the same relative prices of capital and labor, would combine the two factors in exactly the same proportion is called by Minhas the crossover point. The position of the crossover depends on the slope  $(\beta+1)$  and the level  $\left(\frac{\alpha}{A}\right)$  of each of the two curves. If the slopes of the two lines—that is, the elasticity of substitution between capital and labor in the two industries—happen to be exactly the same, the capital intensities of both industries will be identical throughout if the levels of both the lines happen to be also equal; otherwise, they will be parallel, which means that the capital-labor ratio in one of the two industries will be higher throughout than in the other. In case the elasticities are unequal, that is, the slopes of the two lines differ, they must necessarily intersect somewhere. The crossover points might, however, be located to the right or to the left of the usual or even possible range of observed capital-labor or price ratios. In this case, one industry can still be, for all practical purposes, unequivocally characterized as using more capital per unit of labor than the other.

Minhas sets out to demonstrate that, in fact, crossovers can be expected to occur within the practically relevant range so often as to vitiate the analytical usefulness of conventional distinctions between capital- and labor-intensive industries. I cannot agree with this and will now try to show that Minhas' own empirical evidence justifies the opposite conclusion.

To demonstrate the importance of the crossovers, Minhas fits, by a very ingenious procedure, C.E.S. production functions to 24 industries distributed over 19 different countries. The approach is cross-sectional; the primary data (presented in his Appendix I) consist of "value added produced per man year of labor input" and "annual wage rate payment per worker" compiled from official statistical publications for each industry in each country. Ingenuity is called for because no information on corresponding capital inputs or prices is used in the process. Values-added, i.e., the gross revenues minus the costs of materials, are used throughout to represent the outputs,  $V$ . All wage rates and values-added are converted to U.S. dollars in accordance with the fixed official or free market exchange rate.

On the assumption that the real wage rate paid equals the marginal productivity of labor,  $w$  can be substituted for  $\frac{\partial V}{\partial L}$  on the left-hand side of (2a). The resulting equation can be written in the form of the following log linear relationship:

$$(10) \quad \log \left( \frac{V}{L} \right)_i = \log a_i + b_i \log w_i$$

$$\text{where } \log a_i = -\log \alpha_i \frac{1}{\beta+1} \quad \text{and} \quad b_i = \frac{1}{\beta+1} \equiv \sigma_i.$$

Subscript  $i$  identifies the industry and subscript  $j$  the country. The constants,  $\log a_i$  and  $b_i$ , carry only the industry but not the country subscript since the C.E.S. production function, the shape of which they are supposed to reflect, is assumed to be the same in all the countries.

The magnitude of parameters,  $\log a_i$  and  $b_i$ , can thus be estimated by fitting a least-squares regression line through the scatter of  $\log \left( \frac{V}{L} \right)_j$  on  $\log w_{ij}$ , with a fixed  $i$  and varying  $j$ . The slope  $b_i$  of that regression line represents the elasticity of substitution between labor and capital in the  $i$ th industry. Among the 24 regression lines fitted by Minhas, the estimated magnitude of  $\sigma_i$  ranges from 0.7211 in Dairy Products to 1.0114 in Primary Nonferrous Metals; in 20 instances it exceeds 0.8, and in eight of these it lies above 0.9.

To determine the location of potential "crossover" points marking the reversal in the relative capital-labor intensity of any two of the 24 industries, it is necessary to draw up for each one of them a log linear relationship between  $\frac{K}{L}$  and  $\frac{w}{r}$  as described in equation (9) and shown in Figure 1.

The elasticity of substitution between capital and labor determines, however, only the slope of the straight lines drawn on that graph. Their levels depend on the value of the two other constants,  $\alpha_i$  and  $A_i$ , entering in the C.E.S. function of each industry,  $i$ . Equation (10) in addition to  $\beta_i$  (and, consequently,  $\sigma_{ij}$ ) yields an estimate of  $\alpha_i$ —the constant associated in the C.E.S. production function (1) with the labor input,  $L$ —but it is incapable of supplying also an estimate of  $A_i$ , which is the corresponding constant associated with the capital input,  $K$ .

To apply an analogous procedure in estimating the  $A$ 's, it would be necessary only to replace the ratio  $\frac{V}{L}$  on the left-hand side of (10) by the corresponding ratio  $\frac{V}{K}$ , and on its right-hand side replace the wage rate,  $w_{ij}$ , by  $r_{ij}$ , i.e., the rate of profit earned per unit of capital employed by industry  $i$  in country  $j$ .

Minhas presents the estimates of both the  $\alpha$ 's and the  $A$ 's for only six of the many industries covered by his elasticity computations. The magnitudes of the  $\alpha$ 's and  $\sigma$ 's entered in small Table IV correspond exactly to the least-squares estimates of these parameters—based on equation (10)—shown for all the 24 industries in his Tables I and II. No word is said, however, in explanation of the origin of the estimates of the six corresponding  $A$ 's. This is the more surprising since the examination of the five "crossovers" between the capital-labor intensities of these particular six industries (shown on his Figures 5 and 6) constitutes the sole and only factual evidence that Minhas can cite in support of his sweeping and emphatic rejection of the conventional distinction between capital- and labor-intensive industries.

As I have said above, in Chapters 5 and 6, Minhas presents a rather detailed statistical analysis of the rates of return on capital invested in the

same industries in different countries. Table XVII on page 92 summarizes the results of his inquiry; it covers 17 industries and five countries: United States, Canada, United Kingdom, Japan, and India. Most of the industries included in the larger set of data which Minhas actually uses to estimate two of the three parameters of the 24 C.E.S. production functions are represented directly or in slightly aggregated form also in Table XVII. The information contained in it can thus be used to estimate the missing third parameter for 17 of the 24 industries covered in his Table I. The two-step procedure I have used is described below.

Parameter  $A_i$  enters as denominator in the middle term of equation (9); for the purpose at hand it suffices to estimate for each industry the magnitude of that entire term, rather than of  $A_i$  alone. Equation (9) can be re-written in the following form:

$$(9a) \quad \log \left( \frac{\alpha_i}{A_i} \right) = \log \left( \frac{w_{ij}}{r_{ij}} \right) - (\beta_i + 1) \log \left( \frac{K_{ij}}{L_{ij}} \right).$$

In estimating the elasticities of substitution, Minhas has already obtained the magnitudes of the corresponding  $\beta_i$ 's. He compiled and used in his computations the wage rates,  $w_{ij}$ ; he also compiled—but apparently did not use for the same purpose—the  $r_{ij}$ 's for 17 industries in five countries.

The magnitude of the capital-labor ratio,  $\left( \frac{K}{L} \right)_{ij}$ , appearing in the second right-hand term of (9a), can be derived by combining the profit-rates data with information on wage rates and value-added per worker,  $\left( \frac{V}{L} \right)_{ij}$ , which, as we have seen above, Minhas uses too. By his own assumption, the value-added in any industry is exactly exhausted by payments to capital and labor employed by it:  $V_{ij} = L_{ij}w_{ij} + K_{ij}r_{ij}$ . Dividing both sides by  $L_{ij}r_{ij}$  and rearranging the terms, we arrive at the following relationship:

$$(11) \quad \left( \frac{K}{L} \right)_{ij} = \left( \frac{V}{L} \right)_{ij} \frac{1}{r_{ij}} - \frac{w_{ij}}{r_{ij}}.$$

With all the magnitudes appearing to the right of the equation sign given, we can compute  $\left( \frac{K}{L} \right)_{ij}$ . Inserted on the right-hand side of (9a), this completes the information required to determine the magnitude of the constant,  $\log \left( \frac{\alpha}{A} \right)_i$ .

I have performed these additional computations for 21 of the 24 industries covered in Minhas' study; all those industries for which his Table XVII supplies an estimate of the rate of return on capital,  $r_{ij}$ . The results are shown on Figure 2. The factor price ratios,  $\frac{w_{ij}}{r_{ij}}$ , inserted in the course of these computations in equation (11) are those recorded for the industry in question in the United States. This means that the magnitude of the con-

stant term,  $\log \left( \frac{\alpha}{A} \right)_i$ , was determined so as to make each one of the straight lines shown on Figure 2 pass exactly through the point describing the combination of factor prices and factor inputs actually recorded for that particular industry in the United States. As should have been ex-

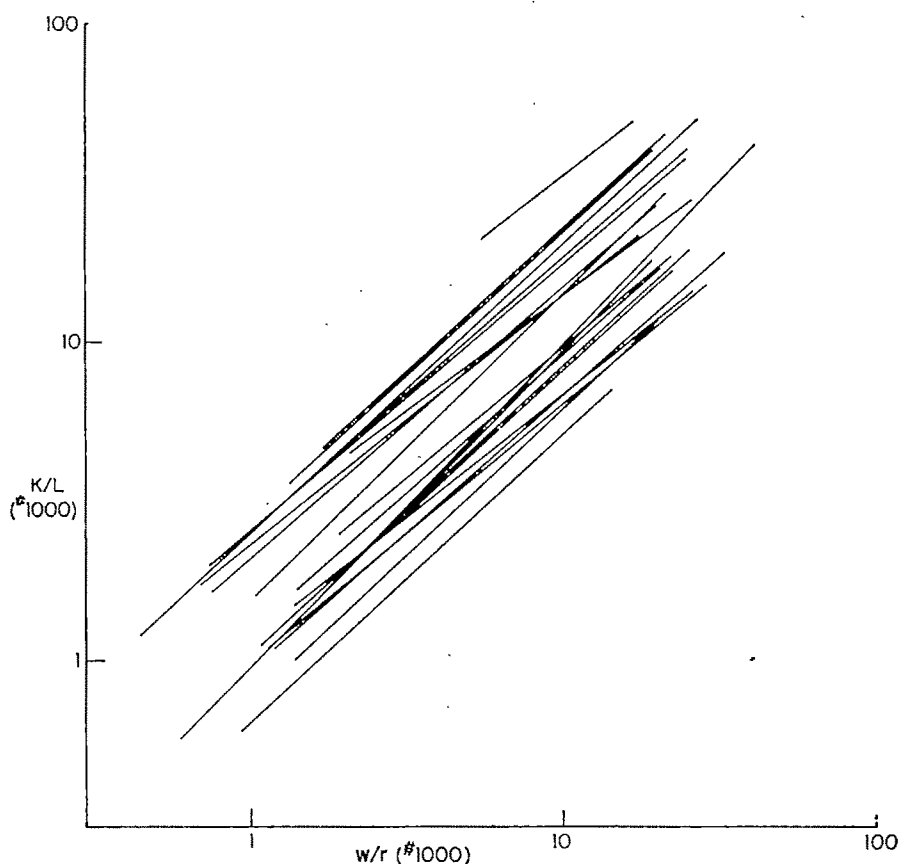

FIGURE 2

pected, all these points are located at the upper right-hand ends of all the 21 corresponding lines. The lowest of the  $\left( \frac{K}{L} \right)_{ij}$  ratios observed in any industry  $i$ —typically observed in India—determine the cutoff at the lower left-hand end of each line. The corresponding lowest factor price ratios,  $\left( \frac{w}{r} \right)_i$ , would have been equal to the wage-profit ratio actually observed in India if the theoretical assumption on which these computations are based were faultless and the empirical information error-free. In

fact, the actual ratios deviate, of course, from those predicted on the assumption that the U.S. price and input ratios lie exactly on the curve.

The picture emerging from supplemental computations as shown on Figure 2 does not confirm Minhas' emphatically stated conclusion that "the strong factor intensity assumption, the conventional distinction between capital and labor intensive industries is of limited practical validity." On the contrary, it seems to confirm the conventional view. Of the theoretically possible 210 crossover points between the 21 lines entered on the graph, only 17 are found to be located within the wide range of factor price ratios, spanned on the one end by those observed in the United States and on the other by those reported from India. Moreover, most of these crossovers occur between industries whose curves run so close together throughout the entire range that for all practical purposes their capital-labor intensities would be considered identical. With two or three exceptions, each one of the 21 industries represented can be characterized as capital-intensive, labor-intensive, or as belonging to an intermediate group. In the light of this evidence the modern theory of international trade stands vindicated.

To avoid undesirable confusion of related but separable issues, up to this point I have presented Minhas' arguments and examined his conclusions without questioning the general theoretical framework within which they have been set. Interested in demonstrating the practical importance of crossovers, he naturally rejected the Cobb-Douglas function—which excludes crossovers by definition—and reached out for a formula capable of showing their existence. But if this were the principal reason for acquiring one more degree of freedom, the result of my extended computations shown in Figure 2 could easily justify a return to the simpler Cobb-Douglas formula. This suggestion would appear to be even more plausible if in applying the least-square method to estimate the slopes,  $b_i$ , in the log linear equations (10), Minhas had not proceeded on the assumption that only the variable  $\left(\frac{V}{L}\right)_i$  is subject to random errors, while the variable

$w_i$  is not. Had he instead, in fitting the slopes of these regression lines, allowed also for errors affecting the observed magnitudes of  $w_i$ , all estimated elasticities would necessarily turn out to be larger, since in 23 out of the 24 industries examined by him, the magnitudes of the  $b_i$ 's, i.e., the elasticities of substitution, turn out to be less—although in most instances only slightly less—than 1. This means that their values would be still closer to 1—the constant elasticity of the Cobb-Douglas function.

The inverse proportionality (implied by  $b_i=1$ ) between the number of workers employed per unit of output of a particular industry and the wage rate paid to them by that industry in different countries can be explained in entirely different terms. The assumption that a man-year of labor in one part of the world is equivalent to a man-year of labor in any other part, i.e., that the typical worker employed, say, in India is equal in productive efficiency to his similarly employed counterpart in the United States, can be questioned. If such equivalence were the rule rather than an exception,

why should economists studying problems of economic development be so much concerned with investment—or rather the lack of it—in “human capital”?

Let it be assumed, for argument's sake, that an average man-year of labor employed by a given industry in one country is twice as efficient as a man-year employed by the same industry in another country. The production function in both instances can still appear to be, and actually will be, essentially the same, provided that, in measuring labor inputs for purposes of comparison, we multiply the figure describing the amount of labor absorbed by that industry in the first country by 2. At the same time, for comparison of the real unit costs of labor to that industry, the actual annual wage rate paid by it in the first country would have to be divided by 2. Such a procedure would be analogous to that used by Ricardo in his *Theory of Rent*. He visualized an agricultural production function allowing for several different grades of land and explained the higher price paid for an acre of better land by its proportionally greater efficiency. A similar argument was used recently by Houthakker when he interpreted the difference in the unit price paid by consumers for grades of nominally the same article as a measure of intrinsic qualitative difference.

The elasticity which Minhas estimates by fitting equation (10) to cross-section data measures—if it is interpreted in this sense—not substitution between capital and labor but rather substitution between different grades of labor, or possibly some combination of both. In the first case, the magnitude of the elasticity constant,  $b_i$ , in equation (10), as estimated by him, would necessarily be close to 1.

To determine which interpretation of Minhas' findings is correct, it is necessary to bring information on capital inputs explicitly into the picture. An elaborate comparison of rates of return on capital in different industries and countries can be found in the last two chapters. As I said above, the author nevertheless relies exclusively on the elegant but, even for his own purposes, not sufficiently powerful procedure in the course of which the elasticity of substitution between capital and labor is derived on the basis of information pertaining to labor only.

I have performed the simple numerical manipulations (similar to those described above in connection with the construction of my Figure 2) required to determine the capital-output ratios,  $\left(\frac{K}{V}\right)_i$ , that would match the labor-output ratios,  $\left(\frac{L}{V}\right)_i$ , used in Minhas' own computations. An examination of the resulting scatters shows that, as compared to the corresponding labor intensity, the capital intensity of any given industry varies little from country to country, and only in a few instances could one discern a visible negative relationship between the two. The over-all picture is thus quite different from that which emerges from what Minhas calls the straightforward, but which in fact is a rather one-sided, method of estimating the elasticity of substitution between capital and labor.

In the light of closer examination of empirical evidence, fixed capital

and labor coefficients (the latter measured in comparable efficiency units) might after all prove to be more appropriate for description of the specific productive relationships than the C.E.S. function in its general, or its particular Cobb-Douglas, form.

Judging by the practical implication that Minhas draws from it, the formally correct interpretations of fixed capital and labor coefficients as a special case of the C.E.S. function tend to be misleading. Fixed coefficients of production can be interpreted more meaningfully as representing a special case of technological conditions under which the two factors can be substituted for each other, but only within relatively narrow limits: the rate of substitution of capital for labor decreasing sharply and approaching zero whenever the capital-labor input ratio approaches a finite upper limit, but falling and becoming infinitely large when that ratio approaches the—also finite—lower limit. The elasticity-of-substitution concept proves to be a very awkward tool for analyzing this type of situation, and the assumption of constant elasticity of substitution simply breaks down in such a case. If the upper and lower limits of the admissible capital-labor input ratios lie comparatively close together, the average fixed coefficients will give an adequate description of such a technology. A combination of two or more alternative sets of such coefficients would of course do still better.

Except in its degenerate form when  $\sigma=0$ , the C.E.S. function itself represents, as a matter of fact, a special case of homogeneous production characterized by literally unlimited substitution possibilities between factors, thus implying—when these factors are capital and labor—that any amount of a finished product can be obtained with a practically negligible amount of either capital or labor provided the supply of the other factors is large enough. This might be a good enough assumption in aggregative analysis where all possible products and processes of production are subsumed under a single loosely defined production function describing not so much a substitution of one method of production for another as a changing product mix. It is, however, hardly adequate for description of alternative input structures of sharply defined individual industries.

The length of this review testifies to the amount of stimulation an interested reader can find in this slim volume. The questions which the author asks are so well put that they will advance the understanding of factor use by the various branches of production in an international setting even if some of the answers which he gives cannot be accepted.

## COMMUNICATIONS

### The Case for Capital Controls to Relieve the U.S. Balance of Payments

It is doubtful that many economists would disagree that one of the two or three current major economic problems of the United States is the reduction and ultimate elimination of the balance-of-payments deficit, and the accomplishment of this without restraining growth of the domestic economy. Presumably no one would contest the grave seriousness of a failure to show a marked improvement in the balance of payments over the course of the next three or four years or the necessity of reducing the deficit without serious adverse side effects.

It is evident, however, that there is no consensus among economists of what, if anything, should be done to meet the problem. There are two kinds of divergences of opinion: first, between those who believe nothing in the way of positive new policy measures should be undertaken and those who advocate various specific policy remedies; second, among the latter, differences as to what specific measures would be optimal. The primary purpose of this paper is to examine the second issue—what specific measures would be optimal, with the case for measures to reduce the outflow of private capital given special attention.

Interest in measures to reduce the outflow of private capital has been stimulated by the Administration's proposal, now before the Congress, to levy a tax on the purchase of securities from foreigners [H.R. 8000]. I shall not be concerned in this paper with this or any other specific types of measures to reduce outward capital movements, nor with the problems—some of which may be formidable—attending the implementation of such measures. I shall instead concentrate on the theoretical aspects of capital controls, with "controls" understood to embrace any kind of measure, direct or indirect, designed to reduce private capital outflows. Finally, the analysis applies only to long-term capital movements, the special case of short-term movements being excluded from consideration.

Before entering into the discussion of alternative policy measures to correct the U.S. balance-of-payments deficit and of the case for capital controls as the least undesirable alternative, a brief comment on the first issue mentioned above—whether any kind of specific balance-of-payments policy is called for—is in order.

#### *I. Market Correction of the Deficit*

Whether or not it would be wise for specific policy measures to be adopted to relieve the balance of payments depends upon the probability that market forces—operating under present policies—will correct the deficit within a reasonable period of time and without interfering with policies to expand the

domestic economy. Fortunately, the option of relying on market forces is still open, since the reserve position of the United States, together with the various swap agreements and other arrangements among central banks, permit a continuation of the deficit for some time without leading to a crisis situation.<sup>1</sup>

The thesis that market forces can be expected to work in the direction of eliminating the U.S. balance-of-payments deficit, even though (and in part *because*) domestic policies succeed in accelerating the rate of growth in the United States, has been most ably supported by the recent Brookings study under the direction of Walter Salant [6]. However, the study's optimistic projections are based on several assumptions which may or may not be realized. Most critical among these is the assumption that U.S. costs and export prices will fall relatively to those of Western Europe. Because of the large degree of uncertainty underlying this assumption, together with the uncertainty involved in extrapolating into the future functional relationships derived from past behavior, the present writer, as well as numerous others, has argued that the Brookings study's projections are not a sufficiently solid base on which to arrive at policy conclusions [10]. This is, of course, a personal judgment, based on the subjective weighing of how much confidence can be placed in balance-of-payments projections in comparison with the consequences of failure of the projections to be actually realized.

Apart from the question of whether one can confidently expect market forces satisfactorily to solve the payments problem without the aid of additional discretionary policy measures, there is the second question of what particular policy measures would be appropriate and acceptable. If there are acceptable policies that could be adopted to relieve the deficit, the case for relying on market forces to do the job is weakened; if not, the case is strengthened.

## II. *The Criteria of Acceptable Policies*

The crux of the matter, of course, is what constitutes "acceptable" policies. There are three general economic criteria to which, it is believed, most economists would agree. These may be briefly identified as effectiveness, employment, and efficiency. In addition, there is a fourth criterion, essentially non-economic in nature, that I shall call institutional.

The three economic criteria are rather obvious and require only summary explanation. Effectiveness refers strictly to the balance-of-payments repercussions of a measure. It is clearly a primary desideratum, any measure failing substantially to reduce the payments deficit being ineligible for consideration at the outset.

The employment criterion refers to the effects of a measure on domestic employment—or, more generally, on economic growth. Regardless of how effective a given measure might be in reducing the payments deficit, it would be objectionable if it caused serious domestic unemployment or if it was

<sup>1</sup> One must also assume, however, that the deficit does not continue unimproved for so long that fear of eventual drastic measures induces widespread destabilizing speculative actions.

inconsistent with domestic policies for full employment and a reasonable growth rate.

The criterion of efficiency relates to the allocation of resources. Any measure that would tend to interfere with the optimum use of resources or that would aggravate an already existing deviation from the optimum pattern of resource use would violate the efficiency criterion.

Finally, the institutional criterion refers to the feasibility of a policy in the context of the contemporary world and the historical position of the United States in that world. Even though this aspect of policy has no theoretical interest to the economist, *qua* economist, any serious discussion of policy requires its consideration. A policy may not be feasible, in the sense employed here, either because it conflicts with noneconomic objectives that have priority or because it requires institutional changes that for political or other reasons are not acceptable.

An ideal policy would completely satisfy all four of the above criteria.<sup>2</sup> If there were such a policy available, presumably the issue of whether to rely on (uncertain) market forces to correct the payments deficit would disappear. Obviously, however, there is no such "ideal" policy. But there surely are different policies whose degree of fulfillment of the stated criteria vary by wide margins. The question, therefore, remains of whether there are particular measures sufficiently satisfactory to deserve consideration as an alternative to reliance on market forces.

### III. *Alternative Payments Policies*

In pursuing this question, we may begin by listing the major policies, each of which, alone or in combination with others, could conceivably be effective in reducing a payments deficit. The list is as follows:

1. Internal deflation of real income and/or prices.
2. Devaluation and establishment of new fixed dollar exchange rates.
3. Abandonment of fixed dollar exchange rates and acceptance of free or floating rates.
4. Quantitative limitation of imports or increased tariffs.
5. Export subsidies or other devices (tax rebates, etc.) directly to stimulate exports.
6. Reduced foreign military expenditure.
7. Reduced foreign aid.
8. Limitations or penalties on private capital outflows.

The list includes only those policies over which the deficit country has some control and excludes such potentially effective policies on the part of other countries as upward revaluation of currencies, expansionary monetary and fiscal policies, control over capital inflows, etc.

It may appear that one very important possible approach to reducing the payments deficit has been omitted—namely, measures to increase productivity

<sup>2</sup>I am assuming that other welfare criteria—such as those relating to income distribution—are not significantly involved.

while holding the line on wage and profit increases. In the Brookings study [6] this is the principal avenue of the projected improvement over the forthcoming years in the balance of payments.

While it cannot be denied that increases in productivity, accompanied by relatively stable money-wage rates and profit margins, would indeed tend to contribute significantly to improving the balance of payments and, further, would fully meet the other criteria of acceptability, unfortunately such a method is not amenable to discretionary policy determination, at least in the short run. It is true, of course, that different policies may influence differently the rate of productivity increases and the level of factor prices, and that particular policies might be identified as more contributive to economic growth at stable prices than are other policies. But the influence of policies in this area is uncertain, marginal, and, in any event, long-run. It is fairly easy through discretionary policies to *retard* the rate of growth and *increase* money wages and profit margins; it is much more difficult to accelerate the rate of growth while restraining wage rates and profit margins.

These comments do not argue against the pursuit of policies most likely to influence favorably growth with price stability; they only argue against the view that such policies can be expected to have a significant impact within the space of the next few years during which the balance-of-payments problem must in some fashion be solved.

#### *IV. Effective But Otherwise Objectionable Measures*

The first point suggested by an examination of the alternative policies listed is that those which best meet the criterion of effectiveness are the worst from the point of view of one or more of the other criteria. For sheer effectiveness in reducing a payments deficit, internal deflation, abandonment of fixed exchange rates, and quantitative limitation of imports rank at the top. Deflation is the most serious violator of the employment criterion, quantitative limitation of imports is the most serious violator of the efficiency criterion, and abandonment of fixed exchange rates is objected to mainly on the basis of the one noneconomic criterion, institutional. Undoubtedly this is the reason why there is a consensus among economists opposing deflation and import controls but far from a consensus opposing free exchange rates. Disagreement over the abandonment of fixed rates as a method of eliminating the payments deficit arises in part out of differences in opinion as to the merits of fixed rates versus free rates in encouraging an optimum level of world trade and investment [2] [3] [4, Ch. 15] [7]. But this is an economic argument, whereas the more definitive consideration so far as policy-making is concerned is essentially noneconomic in character, embracing such questions as the effect of abandoning fixed rates on the financial and economic (and perhaps political?) leadership of the United States in the Free World. Whatever the economic merits of the case, it would appear that fundamentally changing the system of pegged exchange rates is not at present a feasible choice so long as alternative measures involving a smaller departure from established institutions and practices continue to be available.

### V. Devaluation

If abandonment of pegged exchange rates is not feasible, what about devaluation of the dollar and its repegging at a lower gold content? The employment and efficiency criteria are as well satisfied as they are with floating rates, but the institutional criterion is violated to nearly the same extent as it is with floating rates, and, in addition, devaluation carries the risk of being ineffective in eliminating the payments deficit.

The institutional criterion is not met by devaluation because it would involve a fundamental shock to the present international monetary system based on a gold- and dollar-exchange standard. The status of the dollar as an international monetary "anchor" would in all probability be destroyed if the weight of the anchor were to be allowed to change.

The second objection to devaluation is its potential ineffectiveness. It may be ineffective for either one of two kinds of reasons. The first is that it may evoke counterdevaluations by other countries, especially Western European countries and the United Kingdom, which are the chief international competitors of the United States, and Canada, which is the largest market for U.S. exports.

Assuming the problem of counterdevaluation is overcome, the second reason devaluation may be ineffective is more strictly economic in character, relating to the difficulties of selecting the right degree of change in the international value of the dollar. Various estimates of the amount of overvaluation of the dollar have been made [8], and although these may be reasonable, there is no known way of being certain they do not contain a large margin of error. The danger of too small degree of devaluation can be reduced by choosing the amount of devaluation indicated by the higher ranges of estimated overvaluation. However, in this case the opposite danger is run of ending up with an undervalued dollar, thereby increasing the probability of counteraction by other countries, either in the form of devaluation of their currencies or in the form of various import restrictions. Again, the special international position of the dollar leaves less room for mistakes than in the case of other currencies.

### VI. *Reduction of Foreign Military Expenditure and Aid*

If, as I have so far concluded, there are strong objections to deflation, import controls, abandonment of fixed exchange rates, and devaluation, the field of choice is considerably narrowed. It can immediately be further narrowed by eliminating two other possible measures—reduction of military expenditure and reduction of foreign aid.

There is one common ground on the basis of which both of these latter measures are rendered unacceptable as a means of correcting the payments deficit—they are autonomously determined by noneconomic objectives. They are both instruments of foreign policy and therefore not appropriately determined by balance-of-payments considerations.

A second, though subsidiary, consideration applicable to foreign aid is the ineffectiveness of reductions in significantly contributing to eliminating the payments deficit. Because aid recipients tend to spend most of their grant

and loan dollars directly on U.S. exports, reinforced by the government policy of tied aid, only a fraction of any reduction in aid would be reflected in improvement in the U.S. balance of payments [6, pp. 155 ff.].

### VII. *Export Subsidies*

Theoretically, exports could be increased just as effectively through subsidies—direct or indirect—as through devaluation. Indeed, a uniform subsidy for all exports would be tantamount in effect to a “half” devaluation. (The effect could be made “full” by simultaneously imposing a uniform ad valorem tariff on all imports.) However, the efficiency and institutional criteria are seriously by-passed by export subsidies, and, in addition, the effectiveness criterion is not likely to be met.

Export subsidies are the counterpart of import duties and, like them, distort international cost-price comparisons which underlie the optimum allocation of resources internationally. And, again like import tariffs, subsidies go counter to the prevailing and generally accepted code of commercial conduct. Finally, the balance-of-payments effectiveness of subsidies is rendered doubtful because of probable retaliation by other countries, either in the form of increased import tariffs against the subsidizing country's goods or in the form of subsidies on their own export goods.

### VIII. *Capital Controls*

The last remaining measure to investigate is control over capital outflows. While there are certainly serious objections to this policy, there are reasons to believe they may be less serious, in the context of the present balance-of-payments problem of the United States, than any of the other alternatives available. This conclusion is supported by examining capital controls from the point of view of each of the four criteria of acceptability.

#### A. *Effectiveness Criterion*

Starting with the effectiveness criterion, the first question is to what extent the payments deficit is attributable to private capital movements. In view of the interrelationships among the various items in the balance of payments, it is practically impossible to identify with precision the net role of any one item. But theoretical considerations, plus empirical studies, permit conclusions as to the general nature and direction of the balance-of-payments effect of capital movements.

There are many different possible approaches to explaining the reasons for the U.S. payments deficit, and nearly all of them have been cited [9]. Different approaches may serve different purposes. If the purpose of the analysis is to find appropriate policy measures to correct the deficit, approaches may be broadly classified according to whether the emphasis is on enlarging the current-account surplus or on reducing the autonomous capital-account (including unilateral transfers) deficit.

In terms of the *causes* of the deficit, there is no basis for choosing between these two approaches. One may equally well say either that the deficit is caused by the failure of the “transfer” mechanism or that it is caused by a

too large capital outflow. These are saying the same thing, for a "too large" capital outflow can be meaningfully identified only in terms of a "too small" current-account surplus, and likewise "failure" of the transfer mechanism can be identified only in terms of an insufficiently large current-account surplus.

Capital outflow contributes to a payments deficit to the extent that the outflow does not, directly or indirectly, lead to an equivalent current-account surplus. Conversely, a reduction in capital outflow contributes to eliminating a deficit to the extent that it does not lead, directly or indirectly, to an equivalent reduction in the current-account surplus.

On theoretical grounds, the influence of capital flows on the current account of the balance of payments is in the direction of an accommodation. In the absence of countervailing policies, and with fixed exchange rates, a capital movement tightens money and discourages spending in the capital-exporting country and eases money and encourages spending in the capital-receiving country. However, there is no a priori way of knowing whether these price and income effects will be sufficiently strong in any particular case to bring about a real transfer equal to the money transfer. Either underadjustment or overadjustment may occur, depending upon numerous conditions—such as reserve positions, propensities to spend, institutional ties, etc.—which are a matter for empirical determination [4, Pt. II]. Moreover, and perhaps most important in the modern world, the transfer mechanism may be either reinforced or completely swamped by discretionary policies on the part of monetary and fiscal authorities.

In the case of the United States in recent years, the strain on the adjustment mechanism from capital outflow has been great, and the evidence indicates its failure fully to meet the challenge.

A sharp change in the volume of private long-term capital movements out of the United States occurred in 1956. Compared to an annual outflow averaging about \$0.8 billion during the preceding five years, beginning in 1956 and continuing through 1962 the outflow reached an annual average of about \$2.7 billion [6, pp. 278-79].

The nearly two billion dollars of added annual payments on account of private long-term capital outflow from 1956 onward did not, of course, contribute an equivalent net amount to the payments deficit. Even in the absence of indirect adjustment processes, the outflow of capital can be expected directly to cause an increase of exports of goods and services, especially in the case of direct foreign investments, which ordinarily involve the capital-exporting country's shipment of equipment and materials, the receipt of management fees, etc. Some portfolio investments have similar direct effects—as, for example, when the recipient is a capital-hungry underdeveloped country with close trade ties to the United States.

In addition to contributing to the sending-country's exports, a capital outflow also contributes to current receipts in the form of interest and dividends, and, for direct investments, other "invisible" receipts. However, the benefits of such return flows are received only after some delay, the length of which depends upon various circumstances. The balance-of-payments "payoff" pe-

riod for U.S. direct investments has been estimated as between four to seven years [1, pp. 412-13] [6, pp. 142-46], though under some assumptions with respect to investments in Europe and Canada the payoff period may be as long as 10 to 15 years [1, p. 413]. In the case of portfolio investments, at average rates of return received in recent years, "it will be a very long time before even a single investment outflow is recouped in cumulative interest and dividend receipts" [1, p. 416].

While the lack of complete information on all the relevant variables and functions makes it impossible to specify with precision the net balance-of-payments effect of the outflow of U.S. capital, a careful econometric investigation by Philip W. Bell [1] led to the general conclusion that "Shifts in the flow of private capital, in particular in U.S. private capital flowing overseas, have been a major cause of our deteriorating balance-of-payments position since 1956" [p. 458].

From a long-run point of view, after taking into account return flows, capital movements out of the United States may have a net favorable balance-of-payments effect. Thus, as frequently noted, in recent years U.S. income receipts from past foreign investments have exceeded the annual outflow of new capital. But this is not a particularly relevant consideration if the immediate problem is to reduce the balance-of-payments deficit within the course of the next few years. Receipts from past investments would presumably continue unabated regardless of the level of future capital flows. Any reduction in new capital outflows can therefore be expected to have a favorable balance-of-payments impact during the period for which such a result is critical.

For the purposes of the remaining discussion, I shall assume that the balance of payments of the United States could be substantially improved over the course of the next four or five years by reducing the outflow of private capital.

### *B. Employment Criterion*

Turning now to the second criterion of acceptable policy—the employment criterion—control over capital movements falls in between the adverse effects associated with internal deflation and the favorable effects associated with such measures as devaluation. A reduction in capital outflow would cause an adverse effect on domestic employment to the extent that exports are reduced by the diminished outflow of capital. On the other hand, employment would be increased to the extent that domestic investment expenditure is substituted for foreign investment. Neither effect is likely to be very significant, however, and for practical purposes it is fairly safe to regard the net domestic employment effect as neutral.

There are advantages to balance-of-payments policies that do not directly increase (or decrease) domestic employment. Any policy that simultaneously improves the balance of payments and increases domestic employment is very likely to *decrease* employment in other countries. Thus, devaluation, to the extent that it succeeds in reducing the deficit by decreasing imports and in-

creasing exports, exerts a deflationary impact on other countries. Besides being unfortunate on its own grounds, such foreign effects increase the probability of countervailing measures abroad that would negate the initial favorable balance-of-payments effect.

It may be argued, however, that reduction in the payments deficit inherently involves an adverse foreign employment effect, regardless of the means employed to bring about the reduction. To the extent that the payments deficit is eliminated by increasing the current-account surplus, this is necessarily true. But if the deficit is attacked via the capital account it is a different matter.

Looking at it from the point of view of the capital-recipient countries, a distinction should be drawn between those countries whose rates of domestic investment expenditure is significantly dependent upon foreign capital inflow and those where such is not the case. Generally, the former consist principally of underdeveloped economies, and the latter of developed economies. A decreased inflow of foreign capital may well cause decreased investment in underdeveloped countries and thereby reduced employment opportunities. It is much less likely that total domestic investment expenditure would be significantly affected by diminished capital inflow into already developed countries, such as those of Western Europe.<sup>3</sup>

The unfavorable foreign employment effect of capital controls could be largely eliminated by confining restrictions to capital flows going to developed countries. Since the adverse balance-of-payments effect of capital flows is probably highly concentrated in these particular movements, such selective application of controls would not greatly reduce their effectiveness in improving the balance of payments.

There remain for discussion the efficiency and institutional effects of capital control. Because of the larger issues involved in the former, I shall reserve discussion of it until after the institutional criterion is examined.

### *C. Institutional Criterion*

It must be admitted forthwith that one of the strongest objections to capital control by the United States is the violation it would cause to the principle of freedom in international economic relations. This principle has two aspects, one domestic and the other international.

From a domestic point of view, the United States has a long-established principle that individuals and businesses should be free to invest as they see fit, both at home and abroad. This is part and parcel of a more general philosophy of government and economics, and deviations cannot be taken lightly. Justification for restricting freedom of international investment may nevertheless be found on at least two grounds.

The first is based on another equally valid and accepted principle—namely, that when the national interest demands it, the interests of particular indi-

<sup>3</sup>Of the major recipients of U.S. capital, Canada may be an exception to this general rule. If so, consideration might be given to including Canada in the exemption referred to in the next paragraph.

viduals become secondary. I think it can be maintained that the balance-of-payments problem of the United States is one of critical importance, and, if left unsolved, it could cause great harm to both the domestic and international economy. Therefore, measures that otherwise would be unacceptable may become acceptable, provided they would effectively contribute to its solution.

Support for this position is strengthened by the fact that failure to correct the payments deficit in itself results in a loss of freedom that is in some respects much more serious and extensive than the loss of freedom to invest abroad without restriction. Freedom is of very limited meaning if opportunities for exercising it are absent. The presence of a payments deficit imposes constraints upon domestic policy which, in turn, reduce opportunities for *domestic* investment. Specifically, the payments deficit directly restrains growth of the domestic economy and prevents the adoption of expansionary monetary and fiscal policies which would be capable of creating greater investment opportunities at home.

Turning now to the international aspect of capital controls, again there is the objection that they would go counter to the principle of freedom which the United States has vigorously espoused. However, there are two points to be noted in this connection.

The first is that, unlike quantitative trade controls, control over capital movements is recognized as a legitimate exception to the general principle of freedom of international economic relations. This acceptance is formalized in the "codes" of conduct set out in the charter of the International Monetary Fund.<sup>4</sup>

The second point is that nearly all other countries are currently, or have in the recent past, employed control over capital movements as a device for correcting or protecting their balances of payments. In short, it is a policy both accepted in principle and sanctioned by practice and therefore not subject to legitimate criticism by other countries.

#### D. *Efficiency Criterion*

Finally, we arrive at the examination of capital control from the standpoint of the efficiency criterion. From a strictly economic point of view, this is where the most important issues arise, for freedom of capital movements is strongly embedded in the tradition as a necessary part of the market mechanism allocating resources in an optimal fashion. If it can be shown that capital controls would seriously interfere with the optimum allocation of resources, the economic case against them might be decisive.

The theory of gain from long-term capital movements is well known and requires only brief summary [5]. The optimum allocation of capital resources requires that the marginal net rate of return be equalized in alternative uses, both at home and internationally. If the marginal rate of return is higher in country B than in country A, world output and the national income of A

<sup>4</sup> Section 3 of Article VI of the Articles of Agreement of the International Monetary Fund states that, "Members may exercise such controls as are necessary to regulate international capital movements. . . ."

and B are increased by the movement of capital from A to B until the marginal rate of return is equalized in the two countries.<sup>5</sup>

Under ideal conditions, the flow of capital from areas of lower marginal yield to areas of higher marginal yields will take place in response to market forces. In the real world, these ideal conditions are never completely fulfilled and, indeed, may under particular circumstances fall so far short as to cause a *perverse* movement of capital. The absence of ideal conditions is not, *per se*, a reason for concluding that actual capital movements are undesirable from a welfare point of view or that capital controls are justified. It depends upon the extent and seriousness of deviations from the ideal in particular cases.

In the case of the United States, there is a strong presumption that over the long run she should be a net exporter of long-term capital. But there is a serious question of whether the large increase in capital outflow of recent years can be justified on welfare grounds. Leaving aside the distortion caused by imperfect markets, differential rates of taxation and of subsidies, and similar factors that are always present to some degree, special elements have arisen in the last few years to weaken the presumption that uncontrolled capital movements are desirable.

The first of these special elements is the slowdown in the rate of economic growth of the United States, accompanied by above-normal unemployment, in conjunction with extraordinarily high growth rates and below-normal unemployment in Western Europe. There is little room for doubting that the increased flow of capital—especially in the form of direct investment—to Western Europe has been stimulated by the relative boom conditions there compared to the United States.

Now it can be argued that an outflow of capital induced by more prosperous conditions abroad than at home is perfectly rational and economically desirable from the points of view of both the sending and recipient countries. The sending country finds productive employment for some of its "excess" saving, and the receiving country is supplied with additional resources to relieve the strain on its economy. Even if it actually works this way (see discussion below), however, the benefits derived are not those stemming from a more efficient allocation of resources but rather from a fuller use of resources.

An outflow of long-term capital caused by differences in cyclical stages at home and abroad cannot be defended on the basis of the efficiency criterion. Higher rates of return abroad are in this case not an indication of a relatively greater scarcity. Presumably, such differences in return are temporary and would tend to be eliminated, *without* a flow of capital, as recovery in the capital-exporting country occurs.

In short, the comparison of marginal rates of return is relevant as a guide to proper resource allocation only when the rates are those emerging under full employment both at home and abroad. Such has not been the case dur-

<sup>5</sup> The marginal test may not be adequate in those cases where large flows of capital are economic, even though smaller movements are not, such as movements to underdeveloped countries to finance "social overhead" and infrastructure investment.

ing much of the time of the great increase in capital outflow from the United States in recent years.

The second special element that weakens the objection to capital controls on efficiency grounds has been the distorting influences exerted by the European Economic Community. If it is true, as commonly asserted, that U.S. capital has been attracted to Western Europe in order to get "under" the common tariff wall being erected there, the adverse efficiency effects of tariffs may be only compounded by the movement of capital into the area. If we suppose that capital would not have moved into Europe if a discriminatory tariff wall were not to be created, the actual capital movement cannot be regarded as contributing to the more efficient use of resources.

The third special element interfering with the process of optimum allocation is institutional in character. Compared to the financial markets in the United States, in most other countries they are "thin." It is considerably easier to float new issues in New York than in most other financial centers. The apparent lack of any significant relationship between interest rates in New York and in other centers and the floating of new foreign issues [1, pp. 419-20] suggests that the attraction of New York as a capital market has to do less with the cost of borrowing than the availability of credit and the ease of acquiring it. To the extent that the latter is a function of more developed financial institutions rather than simply of capital supply, there is no assurance that the flow of capital is desirable on welfare grounds.

Finally, I turn to what is perhaps the most important point of all. In order for a money capital movement to result in a more efficient allocation, it must lead to or be accompanied by a *real* capital movement. Real capital movements take the form of net current-account balances. To the extent that a net current-account balance of equal amount (but of opposite sign) to a money capital movement fails to develop, the capital movement aborts. In such cases, the capital outflow is accompanied by a reverse movement of short-term capital of an accommodating character and/or by an outflow of gold. If these are temporary movements, they are normal stages in the process of adjustment, but when they persist it is an indication that adjustment and a real transfer have failed to occur.

It will be observed that the failure of real capital to move with money capital is tantamount to one variety of balance-of-payments disequilibrium. What we are saying, then, is that, if a country incurs a deficit disequilibrium accompanying an outflow of long-term capital, control over the capital outflow cannot be regarded as contrary to the efficiency criterion, for real capital is not in fact being reallocated.

The issue runs deeper than this, however, for it might be argued that if there is an autonomous long-term capital movement out of a country, what is required, on welfare grounds, is not suppression of the movement but rather adjustment of the balance of payments to the movement. This argument is applicable, of course, only on the assumption that the marginal productivity of capital is higher abroad than at home. But even with this assumption, is it a valid argument?

If balance-of-payments adjustment to the capital movement could be brought about by means that have no adverse welfare effects elsewhere in the economy, the answer is unambiguously in the affirmative. But if, in order to match the money capital flow with a real capital movement, other welfare criteria are violated, the argument for allowing the capital freely to move is a "second best" argument of doubtful validity.

The issue therefore comes back to the more general question this paper began with: which of the available alternative approaches to correcting the payments deficit is the most satisfactory? On the basis of the criteria I have proposed, it was concluded that there are no policy measures which would effectively adjust the balance of payments to the current volume of autonomous capital outflow (plus unilateral transfers) without serious violation of one or more welfare criteria. If this is the case, it would appear that control over capital outflow may be a more feasible and acceptable means of balance-of-payments adjustment than attempts to force the current account into equilibrium relationship with uncontrolled capital movements.

#### External Economies and Second-Order Optimality Conditions

This note explores the somewhat surprising relationship between external economies (or diseconomies) and the second-order conditions for maximization of the social welfare function. I shall argue that externalities directly reduce the likelihood that the second-order conditions will be satisfied, thereby significantly complicating the pertinent problems of public policy. I will also suggest that this interconnection helps to explain an

interesting argument about externalities and optimal output levels which has recently been put forth by Professors Buchanan and Kafoglis [2]. These authors have argued by counterexamples, both hypothetical and observed, that, contrary to what is normally assumed, the presence of external economies generated by activity  $X$  need not cause the level of activity  $X$  to be below the social optimum. Even if external economies are generated by their operations, industries or firms may voluntarily produce adequate or even excessive outputs, and consumers whose purchases confer indiscriminate social benefits may nevertheless buy more than the ideal amounts.

This comment should help to substantiate the validity and significance of the Buchanan-Kafoglis argument. However, I will try to show how their contention fits in with the Pigovian position, which these authors question, and how it relates to the corpus of value theory. I shall argue that their result is also a consequence of a more general and rather more disturbing theorem, one which tells us that even the second-order conditions are of little reassurance to the policy-maker who takes a partial and piecemeal approach to the determination of ameliorative measures.

### *I. Second-Order Conditions and Optimal Outputs under External Economies*

It does indeed seem plausible, as Buchanan and Kafoglis point out, that "If a municipal government should cease, forthwith, to provide any collective police protection, individuals would, surely, respond by hiring private policemen [and] . . . quite likely . . . , in such a situation, total resource outlay on providing protection to life and property would be greater than under collectivization" [2, pp. 412-13]. Whether or not one is persuaded by such an illustration, it should at least induce us to review the simple standard argument which seems to lead to contrary conclusions. In equilibrium any consumer or producer will have carried his activity to a point where its marginal private benefit equals its marginal private cost (which, for simplicity, we assume to be equal to marginal social cost). If the marginal social benefit exceeds marginal private benefit, we clearly have  $MSB > MC$ , and it would appear that, from the point of view of society, an increase in the activity level must *necessarily* be beneficial.

There is, strictly speaking, nothing wrong with the argument as it stands. We get into trouble only if we proceed one more step and argue that the optimal output is necessarily larger than the equilibrium output. For there is one very obvious reason why this result may not hold—the second-order maximum conditions may just not be satisfied. In these circumstances there are likely to exist local maxima in the social welfare function, and a move that increases net social benefits may then well lead us toward one of these little hills in the welfare function and away from its global optimum.<sup>1</sup> In other words, the Pigovian argument assures us that *some* benefit

<sup>1</sup> Note that Pigou [6, p. 224] explicitly makes the appropriate reservation: "Disregarding the possibility of multiple maximum positions, I propose . . . to call [the national dividend maximizing output] . . . the ideal output. Under conditions of simple competition, if in any

can be achieved by increasing external-economy-yielding activity levels from their equilibrium values, but it by no means precludes the possibility that still greater gains will sometimes result from restriction of these activities.

So far, we have only expressed a reservation which applies to all of value theory. But in the present context there is more to the story. We shall see presently that there is, in fact, some connection between the presence of external economies and the likelihood that the second-order conditions will somewhere fail to hold. But first I shall offer an explanation for the Buchanan-Kafoglis result which is even (at least to me) more surprising and more disturbing.

## II. *Second-Order Conditions and Partial Policy Measures*

Let us restate the proposition that Buchanan and Kafoglis dispute in somewhat more general terms. Suppose the social welfare function *does* satisfy the second-order maximum conditions and that we are at a point where its partial derivative with respect to activity  $a_1$  (its marginal social benefit) is positive. Then it is a plausible allegation, which seems to be widely accepted, that an increase in  $a_1$  will *not* move us away from the true maximum. In other words, if the second-order conditions hold and  $a_1$  has a positive marginal yield, this statement alleges that one can confidently recommend an increase in  $a_1$  as a step toward the social optimum. Unfortunately, though it is plausible and, perhaps, widely accepted, the proposition is false.

Thus consider the following counterexample.<sup>3</sup>

$$\text{Maximize } W = -2a_1^2 + a_1a_2 - 2a_2^2.$$

Using the notation  $W_{12} = \partial^2 W / \partial a_1 \partial a_2$ , etc., we obviously have:

$$\begin{aligned} W_1 &= -4a_1 + a_2, & W_2 &= a_1 - 4a_2, \\ W_{11} &= -4, & W_{12} &= W_{21} = 1, & W_{22} &= -4, \end{aligned}$$

hence:

$$\begin{vmatrix} W_{11} & W_{12} \\ W_{21} & W_{22} \end{vmatrix} = \begin{vmatrix} -4 & 1 \\ 1 & -4 \end{vmatrix} = 14 > 0, \quad W_{11} < 0, \quad W_{22} < 0$$

so that the second-order conditions are satisfied. Moreover, it follows di-

industry the value of the marginal social net product of investment is greater than the value of the marginal private net product, this implies that the output obtained is less than the ideal output . . . ." It is not clear from this statement that Pigou saw the full significance of his unique maximum assumption. However, he was acutely aware of the policy problems caused by the presence of a multiplicity of local maxima. (Thus see, e.g., [6, p. 140].) Moreover, he seems to have given no recognition to the serious multivariable problems discussed in the next section.

<sup>3</sup> I am deeply indebted to Harold Kuhn for this counterexample. Appendix A, below, describes a model which brings out the economic circumstances implicit in the counterexample. It will also be recognized that our counterexample does not really apply to the strictest form of the neoclassical welfare theorem which does remain valid. This rather narrow theorem is discussed and proved in Appendix B.

rectly by setting the first-order partials equal to zero that the maximum value of  $W$  is attained at  $a_1 = a_2 = 0$ . But  $a_1$  has a positive marginal yield at many points in the positive quadrant, e.g., for  $a_1 = 1$ ,  $a_2 = 5$ , the value of  $W_1$  is 1. In fact this is true for any positive  $(a_1, a_2)$  such that  $4a_1 < a_2$ .

Though this result may shake one of our ingrained articles of faith, it is easy to show diagrammatically how the difficulty may arise. In Figure 1a we see that the surface has a unique maximum at  $M'$ . Yet an increase in  $a_1$  from  $A'$  to  $B'$  simultaneously moves us away from  $M'$  and gets us to a higher point on the surface.

The consequences of this result for the theory of economic policy are rather unpleasant to contemplate. The planner who normally has little if any information about the details of the welfare function is, however, able to identify some activities which yield external benefits (of unknown magnitude). On the basis of this very limited information it is tempting to encourage the expansion of those activities. Our argument shows that though such an expansion will indeed increase welfare, it may lead us to neglect opportunities to obtain far larger social gains. Like the second-best theorem, our result exhibits the pitfalls that beset such piecemeal planning procedures. Even the second-order conditions cannot offer the comforting

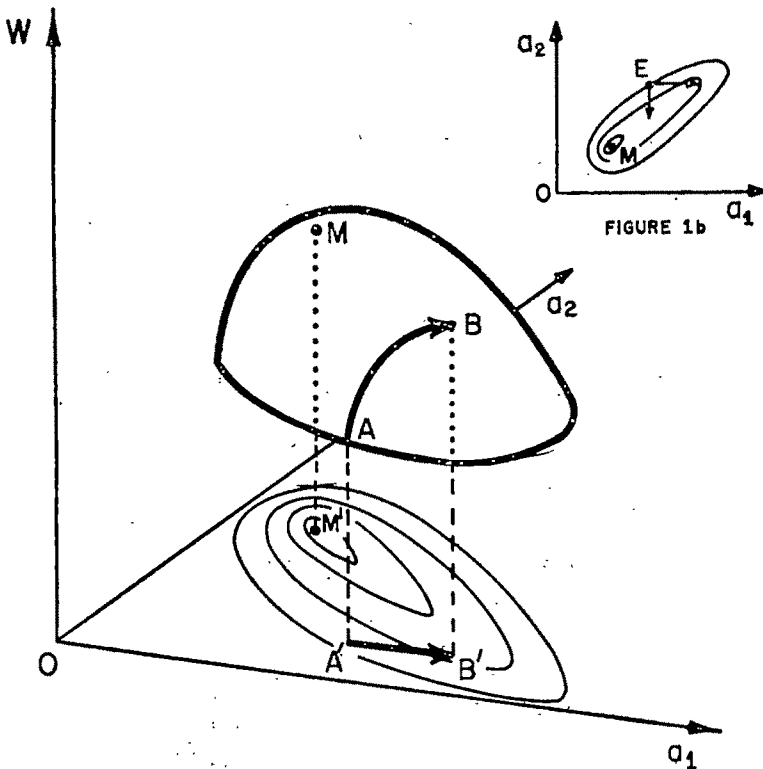

FIGURE 1a

FIGURE 1b

reassurance that a proposal which takes us uphill will really move us toward the top! The standard neoclassical welfare theory, because of its preoccupation with a partial analysis, has thus failed to warn us of what may be a very serious danger.

### III. *External Benefits and the Second-Order Conditions*

Nor are we yet done with our mischief. The policy-maker who concerns himself with externalities may still have some reason to hope that second-order problems will not be added to his concerns. For if the second-order conditions do hold, we can at least be sure that a series of changes that constantly increases social welfare by some nonnegligible amount must ultimately conduct us to the optimal point, even if it does so via a highly circuitous route. But I shall argue now that the very presence of externalities makes it less likely that the second-order conditions will be satisfied. This view seems at a number of points to be close to the surface in the standard welfare discussions. It may have been suggested by the idea that the second-order conditions, in economic terms, require activities to be characterized by diminishing returns. But external economies have gotten themselves associated with increasing returns to scale.<sup>3</sup> It would then seem to follow that the second-order conditions are rendered suspect by the presence of externalities.

It turns out that there is firmer ground for this suspicion, as I shall now demonstrate. In our economy let there be  $n$  agents (individuals, firms),

<sup>3</sup> In part this association results from the context in which much of the early explicit discussion of external economies took place. It will be recalled that one objective in using the concept was to show how, in a decreasing-marginal-cost industry, the firms which constitute it may nevertheless be subject to the increasing marginal costs necessary for them to achieve equilibrium under pure competition. And one explanation advanced was that external economies can produce decreasing costs for the industry even where the cost curve of each of its firms is rising. (See, e.g., Marshall [5, Book V, Ch. 10].) As a matter of fact, there seems to be no general reason to associate external economies with increasing returns in the sense of decreasing marginal costs that result from a rise in the industry's output, though external economies do always tend to reduce an industry's marginal costs *at a given output level*. To show this, let  $T, T_1, \dots, T_n$ , respectively, represent the total cost of the industry and its firms 1, 2,  $\dots$ ,  $n$ , and let  $Q, Q_1, Q_2, \dots, Q_n$  represent the corresponding outputs. Then the industry's marginal cost is

$$M = \frac{dT}{dQ} = d(T_1 + T_2 + \dots + T_n)/dQ = \left( \frac{\partial T_1}{\partial Q_1} + \frac{\partial T_2}{\partial Q_1} + \dots + \frac{\partial T_n}{\partial Q_1} \right) \frac{dQ_1}{dQ} + \dots + \left( \frac{\partial T_1}{\partial Q_n} + \dots + \frac{\partial T_n}{\partial Q_n} \right) \frac{dQ_n}{dQ}.$$

But if a rise of the output of firm  $i$  confers an external economy on firm  $j$  we must have  $\partial T_j / \partial Q_i < 0$ . Therefore, provided  $dQ_i / dQ > 0$ , i.e., so long as the output of firm  $i$  increases with that of the industry, the presence of any such external-economy term  $\partial T_j / \partial Q_i$  must reduce the value of  $M$ .

However, these external benefits do *not* make for increasing returns, i.e., they do not yield  $dM/dQ < 0$ , unless the magnitude of the externalities increases with the output of the industry.

Of course, it is always possible to associate increasing returns with external economies if one follows Bator and simply defines the former to be a subcategory of the latter. Cf. Bator [1, pp. 365-69].

whose activity levels are measured by the variables<sup>4</sup>  $a_1, \dots, a_n$ . Then, given the social welfare function, let the welfare conferred on agent 1 be given by  ${}_1W(a_1, \dots, a_n)$ , etc., and let the social welfare,  $W$ , be the sum<sup>5</sup> of these individual measures:  $W = {}_1W + {}_2W + \dots + {}_nW$ . We may write  ${}_iW_{jk}$  for  $\partial^2 {}_iW / \partial a_j \partial a_k$ . Then if, say, agent 2's activity confers an external economy (benefit) on agent 1, we must have  ${}_1W_{12} > 0$ ; i.e., an increase in  $a_2$  must increase  ${}_1W_1$ , the direct marginal contribution of his own activity to the welfare of agent 1.<sup>6</sup> More generally, a direct external benefit conferred by activity  $j$  on agent  $i$  must involve

$$(1) \quad {}_iW_{ij} > 0.$$

Let us, for the sake of simplicity, assume that we can ignore what may be called "indirect externalities,"<sup>7</sup> i.e., that all

$$(2) \quad {}_iW_{jk} = 0 \quad \text{for all } i \neq j \text{ and } i \neq k.$$

It will be recalled that the second-order maximum conditions require

$$(3) \quad W_{ii} < 0, \quad \begin{vmatrix} W_{ii} & W_{ij} \\ W_{ji} & W_{jj} \end{vmatrix} > 0, \quad \begin{vmatrix} W_{ii} & W_{ij} & W_{ik} \\ W_{ji} & W_{jj} & W_{jk} \\ W_{ki} & W_{kj} & W_{kk} \end{vmatrix} < 0, \dots$$

for all  $i, j, k, \dots$ .

Then we have the following theorems:

**Theorem 1.** In the absence of all direct and indirect externalities and provided all activities exhibit diminishing returns, the second-order maximum conditions (3) will necessarily be satisfied.

**Proof:** In the absence of indirect externalities, condition (2) must hold, and similarly, because there are no direct externalities, we must have all  ${}_iW_{ij} = {}_iW_{ji} = 0$ . Hence, all off-diagonal elements of the determinants in (3) must be zero, so that (3) becomes

$$(4) \quad W_{ii} < 0, \quad \begin{vmatrix} W_{ii} & 0 \\ 0 & W_{jj} \end{vmatrix} > 0, \quad \begin{vmatrix} W_{ii} & 0 & 0 \\ 0 & W_{jj} & 0 \\ 0 & 0 & W_{kk} \end{vmatrix} < 0, \text{ etc.}$$

<sup>4</sup> The possibility that an agent may engage in several activities makes no substantial difference to the argument. Nor is more trouble caused by the fact that it is not always possible to measure the level of an activity by a single number. This is argued in footnote 8, below.

<sup>5</sup> The assumption that the social welfare function is just the sum of the individual welfare functions involves no loss of generality for our purposes. All of the arguments that follow remain valid so long as  $\partial W / \partial {}_iW > 0$  for all  $i$ , i.e., so long as the social welfare is an increasing function of the welfare of each member of the community, for then the signs of the partials of  $W$  with respect to the  $a_i$  remain unchanged.

<sup>6</sup> This definition of "externality" has implicit features that require some examination. These are discussed in Appendix C, below.

<sup>7</sup> E.g., activity 3 must have a negligible influence on the marginal external effects of activity 2 on agent 1.

Since, by hypothesis, diminishing returns hold throughout, we must have  $W_{ii} < 0$  for all  $i$ , and all other conditions in (4) follow at once.<sup>8</sup>

We may also prove:

**Theorem 2.** If there are some external economies and no diseconomies present in the system (or some external diseconomies and no external economies), then if the externalities are of sufficient magnitude, the second-order conditions (3) will be violated.

*Proof:* Suppose we have  $W_{ij} > 0$  and all  $W_{rr} \geq 0$ . Since  $W_{ji} = W_{ji} + W_{ji} > 0$  and, similarly,  $W_{ij} > 0$ , then we must have a negative second-product term in the determinantal expansion,

$$\begin{vmatrix} W_{ii} & W_{ij} \\ W_{ji} & W_{jj} \end{vmatrix} = W_{ii}W_{jj} - W_{ji}W_{ij}.$$

But because there are no diseconomy components to balance off the external-economy components, sufficiently strong externalities, i.e., sufficiently large  $W_{rr}$ , will, *ceteris paribus*, render the value of this determinant negative, thus violating one of the second-order requirements, (3).

Thus we see that there is a rather strong connection between externalities and the second-order conditions, but that external diseconomies can be just as troublesome in this respect as can external economies.<sup>9</sup>

#### IV. Externalities and Second-Order Relationship: Explanation

Though the source of the relationship between the presence of externalities and the second-order conditions is not immediately obvious, an intuitive explanation can be provided. First, it is easy to offer an illustrative

<sup>8</sup> If there are several activities per person but no externalities, and the second-order conditions are satisfied for each individual, then, even though not all off-diagonal elements need be zero, the second-order conditions for the social welfare function must still necessarily be satisfied. For the matrix of the second-order conditions may then be partitioned into

$$\begin{pmatrix} \alpha_1 & 0 & \cdots & 0 \\ 0 & \alpha_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \alpha_k \end{pmatrix}$$

where each  $\alpha_i$  is a matrix whose principal subdeterminants all satisfy the second-order conditions and, therefore, the product matrix  $\alpha_1, \alpha_2 \cdots \alpha_k$  must also do so.

<sup>9</sup> I must be careful to avoid implying that Buchanan and Kafoglis' counterexamples and arguments can all be classed under the theorems of Sections II and III. They point out, justly, that a number of writers on welfare economics (myself, no doubt, included) have carelessly equated the desirability of an increased output by some industry with an injunction to increase the allocation of resources to that industry. But if the increased outputs are produced under central management because of the externalities, it may be that their mode of manufacture can be reorganized in a more efficient manner so as to obtain larger outputs from smaller inputs. Surely that is the rationale behind the Buchanan-Kafoglis example where there is reduced employment of policemen when a central authority takes over the function of police protection. There is very likely a larger output (increased safety for the citizen), but it takes smaller input quantities (fewer police officers) to achieve this happy result.

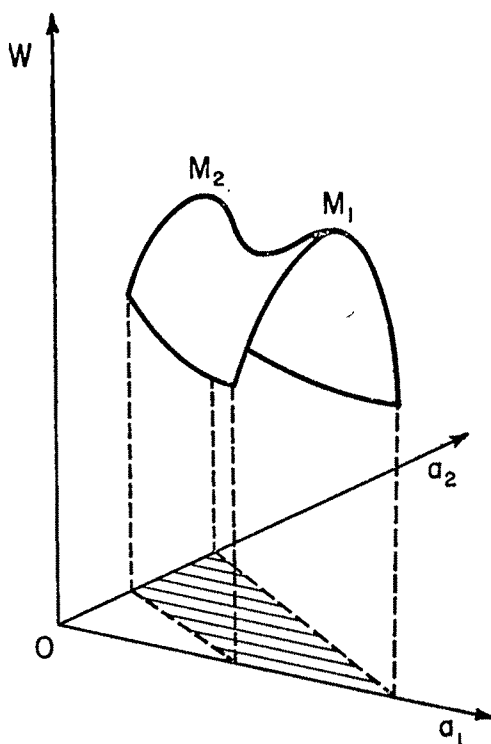

FIGURE 2. EXTERNAL DISECONOMIES

algebraic relationship by means of a slight modification of an earlier example,

$$W = -a_1^2 + ka_1a_2 - a_2^2,$$

to which we can always add a constant term (without changing the analysis) to make sure that some activities yield a positive amount of total welfare. On our criterion, this function yields external economies if  $k > 0$  and diseconomies if  $k < 0$ . Moreover, our determinantal second-order conditions show that this relationship violates the second-order conditions if either  $k > 2$  or if  $k < -2$ .

We next examine the two types of case graphically. In Figure 2 an external-diseconomies welfare function that violates the second-order conditions has been plotted, while Figure 3 represents the corresponding external-economies case. The first of these figures shows that local maxima may be expected to lie directly above the axes, i.e., at  $M_1$  and  $M_2$ . The reason for this is that at such a point one of the activities, e.g.,  $a_2$  is abandoned altogether, so that its deleterious effects on the yield of the other activity,  $a_1$ , is eliminated. The returns to  $a_1$  will therefore be at a maximum at points above the  $a_1$  axis, and we therefore need not be surprised to find a maximum,  $M_1$ , there, and a corresponding explanation applies to  $M_2$ .

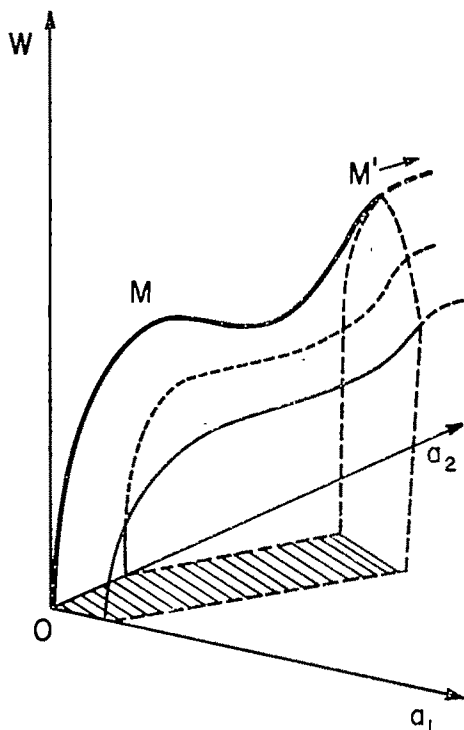

FIGURE 3. EXTERNAL ECONOMIES

In the external-economies case, the graph of a somewhat more complex relationship has been drawn to produce a *plausible* illustration of a multiplicity of optima. Here, as  $a_1$  increases, it adds to the welfare productivity of  $a_2$  and vice versa. As a result welfare may even increase without limit with the levels of  $a_1$  and  $a_2$  so that a maximum,  $M'$ , may occur at the highest levels of activity permitted by the available resources. Or, if the magnitude of the externality,  $W_{12}$ , decreases sufficiently after some point or if the diminishing returns terms,  $W_{11}$  and  $W_{22}$ , increase sufficiently in absolute value, we may obtain an interior maximum at some combination of high levels of activity,  $a_1$  and  $a_2$ . On the other hand, we can obtain a second maximum,  $M$ , corresponding to lower values of  $a_1$  and  $a_2$  if at that level the externalities have not yet risen sufficiently to offset the diminishing returns to each activity taken by itself.<sup>10</sup> This interpretation offers one comforting sop to the policy-maker, one which is, at least in spirit, at variance with the Buchanan-Kafoglis conclusions. For it tells us that, if external economies are sufficiently strong and sufficiently persistent, it will indeed pay society

<sup>10</sup> The reader can construct for himself an even more simple-minded externalities case by moving the surface in Figure 2 so that point  $M_2$  goes through the origin, and  $M_1$  lies above a 45° line through the origin in the  $a_1a_2$  plane. Here production or any other activity constantly decreases welfare until the levels of the activities are sufficiently high to yield significant external benefits.

to increase all activity levels indefinitely. For, speaking loosely, the social welfare function will then have its maximum at infinity. Unfortunately, no such simple-minded approach suggests itself for the diseconomies case where the number of local maxima may well grow with the number of individuals in the society, and where there seems to be no easy way to select among the very large number of maxima which may be encountered. 11~

#### V. Concluding Comment

It would appear, then, that Buchanan and Kafoglís have raised a fundamental point in questioning whether external economies need always call for increased outputs, and in doing so they have led us to recognize a number of ways in which we may have been misled by the received welfare analysis. While our theoretical writings often readily assume that the second-order conditions hold, the very presence of externalities may be taken to cast doubt on the validity of that premise. But where the premise fails, the increased-output argument loses its force and intuition becomes a very treacherous guide for the policy-maker. One may well suspect that the presence of externalities may sometimes even cause the second-order conditions to be violated throughout the relevant range. In that case there will exist no interior optimum points. And it is well known that where a number of alternative corner points serve as competing local optima, going uphill (i.e., increasing output because that moves us to a higher point on the social welfare surface) is apt to be a particularly unreliable procedure for getting to the global maximum. Worse still, it transpires that, in a multi-variable world, guidelines for action may not be much clearer even if the second-order conditions hold. The planner's task may be compared to an attempt on a foggy day to get to the highest point on what, for all he knows, may be the top of a ridge or the rim of a crater. Just going uphill may well take him in a very wrong direction.

WILLIAM J. BAUMOL\*

#### APPENDIX A: A COUNTEREXAMPLE MODEL

It is by no means obvious how externalities or the neoclassical considerations on the allocation of the economy's limited resources are reflected in the counterexample equation of Section II or in Figure 1, by means of which it is shown that a commodity whose output yields external benefits may be produced in overoptimal amounts by a free market, even if the second-order conditions are satisfied. Though only two activities,  $a_1$  and  $a_2$ , enter the equation or the diagram, these assume implicitly that there is a third activity,  $a_3$ , at whose expense it is possible to increase  $a_1$  and  $a_2$ . This is why the transformation function (the production possibility function) does not appear.

This can be shown with the aid of the following model. Though most of

\* The author is professor of economics at Princeton University. He is indebted to the National Science Foundation whose grant was extremely helpful in the completion of this paper. He is most grateful to Harold Kuhn, Edward Pearsall, Richard Quandt, and Allan H. Williams for their very useful comments and suggestions.

the literature refers to a competitive economy containing many individuals and many small firms, it is convenient in our counterexample to let our economy be composed of only three individuals who behave like pure competitors. We may represent their respective activity levels by  $a_1$ ,  $a_2$ , and  $a_3$  and their welfare functions by  ${}_1W$ ,  ${}_2W$ , and  ${}_3W$ . Let these functions be given by

$${}_1W = 2a_1a_3 - a_1^2 + a_2^2 + 14a_1 + 22a_3$$

$${}_2W = 5a_1a_2 - a_2^2 + a_3^2 - 14a_1 + 5a_2$$

$${}_3W = 2a_2a_3 - a_3^2 + a_1^2 - 5a_2 - 22a_3.$$

It will be noted that these functions contain a number of transfer payments. For example, an expansion in the level of activity  $a_1$  yields 14 (dollars?) to individual 1, but this amount is simply taken from individual 2 (the term  $14a_1$  occurs in  ${}_1W$ , and the term  $-14a_1$  appears in  ${}_2W$ ). Hence, here is a payment to individual 1 which yields no corresponding net social gain.

It is also convenient for simplicity of our relationships to measure activity levels  $a_1$ ,  $a_2$ , and  $a_3$ , not in absolute terms, but as deviations from their optimal levels, so that, e.g.,  $a_3 = -6$  means only that activity 3 is 6 units below its optimal level and that welfare maximization will require  $a_1 = a_2 = a_3 = 0$  as we shall see presently.

Differentiating each individual's welfare function in turn with respect to his own activity (and writing, e.g.,  ${}_1W_1$  for  $\partial {}_1W / \partial a_1$ ) we obtain

$${}_1W_1 = 2a_3 - 2a_1 + 14$$

$${}_2W_2 = 5a_1 - 2a_2 + 5$$

$${}_3W_3 = 2a_2 - 2a_3 - 22.$$

Since in atomistic equilibrium each individual will act independently to maximize his own welfare, this requires  ${}_1W_1 = {}_2W_2 = {}_3W_3 = 0$ . Hence, setting each of the preceding equations equal to zero and solving, we see that the competitive activity levels will be  $a_1 = 1$ ,  $a_2 = 5$ , and  $a_3 = -6$ .

Now adding the three individual welfare functions together to obtain the social welfare function,  $W$ , we have

$$W = {}_1W + {}_2W + {}_3W = 2a_1a_3 + 5a_1a_2 + 2a_2a_3.$$

Let the social transformation function be given by

$$a_1 + a_2 + a_3 = 0.$$

Using this to eliminate  $a_3$  from the social welfare function, it becomes

$$W = -2a_1^2 + a_1a_2 - 2a_2^2,$$

which is the welfare function of the counterexample in Section II. Moreover, at the competitive equilibrium point where  $a_1 = 1$  and  $a_2 = 5$ , we have as the social marginal yields of these activities,

$$W_1 = -4a_1 + a_2 > 0 \quad \text{and} \quad W_2 = -4a_2 + a_1 < 0,$$

so that  $a_1$  yields external benefits and  $a_2$  yields external diseconomies, even though *both* the activity levels exceed the social welfare maximizing levels,  $a_1 = a_2 = 0$ . (That these are the optimal values may be verified by direct differentiation of our social welfare function  $W = -2a_1^2 + a_1a_2 - 2a_2^2$ .)

#### APPENDIX B: PROOF OF THE NEOCLASSICAL EXTERNALITIES THEOREM

It should be made clear that the arguments of the text do not conflict with what may be called the *strict* neoclassical externalities theorem—a theorem which this appendix will show to be true if the second-order conditions hold. This theorem can be restated as follows:

Suppose all activities are at their competitive equilibrium levels and that activity  $a_1$  generates external benefits (so that  $W_1 > 0$ ), but that *none of the remaining activities yields any externalities* (so that  $W_2 = \dots = W_n = 0$ ). Then the socially optimal value of  $a_1$  must be greater than its equilibrium level.

It will be shown presently that the presence of any externalities—either economies or diseconomies—can invalidate the result. Unfortunately, then, the modest assertion of this strict externalities theorem is not terribly helpful to the policy-maker in a world where externalities and departures from equilibrium pervade the economy.

To prove the theorem we will assume that the social welfare function,  $W = f(a_1, \dots, a_n)$ , is everywhere strictly concave<sup>11</sup> (concave downwards).

Thus we are given:

(i)  $W = f(a_1, \dots, a_n) = f(A)$  is strictly concave.

(ii) The function has a maximum (which by our concavity assumption is necessarily unique and absolute). This maximum occurs at

$$A_{\max} = (a_1^{\max}, \dots, a_n^{\max}) \quad \text{where} \quad f(A_{\max}) = W_{\max}.$$

(iii) The function has an equilibrium point,  $A_{eq} = (a_1^{eq}, \dots, a_n^{eq})$ , where  $f(A_{eq}) = W_{eq}$ , and at which  $\partial(f/\partial a_1) > 0$  and  $(\partial f/\partial a_j) = 0$  for  $a_1 = a_1^{eq}$ ,  $a_j = a_j^{eq}$ ,  $j = 2, \dots, n$ .

We wish to prove  $a_1^{\max} > a_1^{eq}$ .

*Proof* (see Figure 4): Suppose the contrary, that  $a_1^{\max} \leq a_1^{eq}$ , and let  $U$  be the vector  $U = (1, 0, \dots, 0)$ . Then, by (iii),

(iv)  $W_{eq+\delta} = f(A_{eq} + \epsilon U) > f(A_{eq})$  for sufficiently small  $\epsilon > 0$ . Moreover, by (ii),  $f(A_{\max}) > f(A_{eq})$  and so, by (i) and (iv),

(v)  $f(A) > f(A_{eq})$  for all  $A$  on the line segment joining  $W_{\max}$  to  $W_{eq+\delta}$ .

Now, by our assumption  $a_1^{\max} \leq a_1^{eq}$ , and because  $a_1^{eq} < a_1^{eq} + \epsilon$ , there exists a point  $C = (C_1, \dots, C_n)$  on the line segment joining  $W_{eq+\delta}$  to  $W_{\max}$  and lying in the hyperplane  $a_1 = a_1^{eq} = \text{constant}$ .

But since  $W$  is strictly concave, so is its intersection ( $RS$  in Figure 4) with the hyperplane  $a_1 = a_1^{eq}$ . By (iii) it follows that  $W_{eq}$  must be the absolute maximum on this intersection so that

<sup>11</sup> Concavity of a differentiable function is tantamount to its satisfying the second-order maximum conditions. The reader will recall that a function is defined to be strictly concave if it passes the following test: Let  $A$  and  $B$  be any two points on the graph of the function, and let  $AB$  be the straight line segment connecting  $A$  to  $B$ . If every point (except the end points) of line segment  $AB$  lies below the graph of the function, then the function is strictly concave.

of the marginal private net product, this implies that the output obtained is less than the ideal output . . . [6, p. 224].

It seems strange in retrospect that there has apparently been no previous attempt to prove the Pigovian theorem, considering how often it has been discussed (and slightly amended).

#### APPENDIX C: ON THE DEFINITION OF "EXTERNALITY"

It transpires that it is not quite as easy to provide a usable formal definition of "externality" as might at first appear. This appendix offers some remarks on this subject and comments on some peculiarities in the use of the term which has been made in this paper.

Two implicit features of the definition of "externality" employed in this note should be brought to the reader's attention:

1. The usual externality concept asserts that agent 1's activity affects the *total* welfare of some other individual, ( ${}_1W_1 \neq 0$ ), and does not necessarily imply that agent 1's activity influences the *marginal* return to the activities of the other individual, 2, ( ${}_2W_{12} \neq 0$ ). However, in this note the latter, marginal criterion ( ${}_2W_{12} \neq 0$ ) is employed throughout. Clearly the two criteria do not necessarily yield the same results: e.g., if the welfare function of individual 2 is  ${}_2W = K a_1 / a_2$  (where  $a_1$  again measures the activity level of individual 1, etc.), then  ${}_2W_1 = K / a_2 > 0$ , so that in the conventional sense external economies are present; but  ${}_2W_{12} = -K / a_2^2 < 0$ , so that in terms of my usage individual 2's activity produces external diseconomies. Nevertheless, both in principle and in practice, the two criteria are not unrelated. Thus if for  $a_2 = 0$ , the total welfare of the second individual,  ${}_2W$  is unaffected by  $a_1$ , and if  ${}_2W_{12} > 0$  throughout, then we must have  ${}_2W_1 > 0$  for all  $a_2 > 0$ . That is, if the  $y$  intercept of 2's welfare function does not change but its slope (marginal value) rises throughout, then his *total* welfare must also increase to the right of the  $y$  axis. More important, most if not all of the examples of external economies which are found in the literature involve *both*  ${}_2W_1 > 0$  and  ${}_2W_{12} > 0$  (with a corresponding assertion holding for diseconomies). For example, if an increased output by firm 1 makes it easier for company 2 to obtain skilled workers or some other specialized inputs, then both the total and marginal costs of company 2 may be expected to fall.

It will be noted that my externality concept then rules out the relatively uninteresting case Davis and Whinston [4] have called "separable externalities," i.e., externalities which involve  ${}_2W(a_1, a_2) = {}_2W^*(a_1) + {}_2W^{**}(a_2)$  so that, necessarily,  ${}_2W_{12} = 0$ .

2. A second important element in the definition of an externality has, with one noteworthy exception, been overlooked in most of the formal definitions which are found in the literature. It has become customary to take the easy option and equate externalities with interdependence—that is, an externality is defined to exist if, and only if, individual 2's welfare is affected by the level of individual 1's activity. In fact, such a definition of an externality robs it of its most important welfare implications. For an

externality in the Marshallian or Pigovian sense exists *only if proper compensation is not paid* to the actor so that his private marginal gain is not equal to the marginal social gain. Only this sort of externality produces a nonoptimal competitive equilibrium. Thus, interdependence is a necessary but not a sufficient condition for the significant classical externality concept.<sup>13</sup>

Strictly speaking, the assertion that marginal social gain differs from the marginal private gain requires information about the effects of the activity in question upon at least two persons: the effects upon the actor, 1, and the effects on 2, the person whose welfare is influenced by 1's activity. For without such information we cannot judge whether or not 1's marginal gain equals that of the group (1 and 2 together). Following Buchanan and Stubblebine [3], we may then conclude that a pair of sufficient conditions for the existence of an externality (they call it a Pareto-relevant externality) require (a) that the actor, individual 1, be in equilibrium with respect to his own activity, so that  ${}_1W_1=0$ , and (b) that the marginal effect of his activity on individual 2 be nonzero, i.e.,  ${}_2W_1\neq 0$ . Thus, throughout the preceding note it is assumed implicitly that each individual is in equilibrium so that no *ceteris paribus* marginal change in his activity will produce any change in his own welfare. For then we can be sure that, if a marginal change in his activity does affect the welfare of others, its private payoff (zero) must differ from its yield to society.<sup>14</sup>

#### A Note on Progression and Leisure

One of the most widely accepted conclusions of tax theory is that more progression in an income tax leads to less work effort. The conclusion may be formally stated as follows: on the assumption of declining marginal util-

ities of income and leisure, a rational individual will choose to work fewer hours if a proportional income tax is replaced by a progressive tax with an equal yield. There are two versions of what is meant by "equal yield" in this context. The first, as used by O. von Mering, stipulates that the worker would pay the same amount of tax under progression if hypothetically he continued to work the number of hours chosen under the proportional tax [2, pp. 113-14; pp. 454-55 in reprint]. The second version, which has been used by R. A. Musgrave, K. E. Boulding, and A. Williams, stipulates that the worker will in fact pay the same amount of tax after having adjusted his work hours in response to progression [3, pp. 241-43] [1, pp. 824-26] [4, pp. 65-69]. Equality of yield has therefore been defined both *ex ante* and *ex post* by the writers on this subject, but both definitions have led to the same conclusion regarding the effect of progression on work effort.

It is the purpose of this note to show that the conclusion follows irreproachably if an *ex ante* definition of equal yield is used, but needs to be qualified if an *ex post* definition is used. Given only the assumptions of rationality and declining marginal utilities, it is possible for an *ex post* equal-yield progressive tax to result in more work effort.

## I

The model for the analysis is depicted in Figure 1. The worker has an endowment of  $OA$  hours which he can use for work or leisure. The wage-rate before tax is  $OB/OA$ . After a proportional income tax at the rate of  $CB/OB$  is imposed, the opportunity-line or wage-line pivots from  $AB$  to  $AC$ . The worker maximizes welfare by distributing his hours between work and leisure in such a way that the ratio of the marginal utility of leisure to the marginal utility of income (the slope of an indifference curve) is equal to the marginal wage-rate net of tax (the slope of the wage-line). He therefore locates himself at  $D$ , choosing  $OE$  hours of leisure and  $EA$  hours of work, receiving a gross income of  $FE$  and paying a tax of  $FD$ .

We now consider the consequences for work effort of substituting various types of progressive taxes for the proportional tax. There is first the progressive tax discussed by von Mering: one which provides *ex ante* an equal yield. Such a tax gives rise to a wage-line of the form  $AGDH$ . The single kink in the line at  $G$  indicates that in our example the progressive tax is applied to two brackets of income. It is clear from the pattern of indifference curves associated with declining marginal utilities of income and leisure that the new point of tangency must lie on  $DGA$  to the right of  $D$ . Less work effort is entailed. To the worker located initially at  $D$ , the new tax presents a raised marginal rate and an unchanged average rate. There will therefore be a substitution effect adverse to work effort and no income effect at all, and von Mering is correct in asserting that in this case "a progressive income tax tends to decrease efforts more than a proportionate income tax" [2, p. 114; p. 455 in reprint].

## II

It is also evident that the *ex ante* equal-yield tax will produce a smaller yield *ex post*. We now turn to the progressive taxes which produce *ex post*

tax of this type will produce *ex post* an equal yield as a result of stimulating work effort. The wage-line  $APQ$ , which is tangent to the indifference curve  $i_2$  at  $R$  on the equal-yield line, illustrates this case.

It can readily be shown by geometrical reasoning that an equilibrium at  $R$  is consistent with our stated assumptions. The slope of the progressive-tax wage-line at  $R$  can be greater than the slope of the proportional-tax wage-line  $D$  if the degree of progression is sufficiently mild. The slope of  $i_2$  at  $S$  is less than its slope at  $R$  but may still be greater than the slope of  $i_1$  at  $D$  if the marginal utilities decline slowly enough. If the slope of  $i_2$  at  $S$  exceeds the slope of  $i_1$  at  $D$ , the geometrical requirements of the assumption of declining marginal utility of income are satisfied. The assumption of declining marginal utility of leisure implies that the slopes of indifference curves be successively steeper moving leftwards along a horizontal line, and this requirement is also satisfied in our example.

#### IV

The geometrical reasoning suggests that increased progression will induce more work effort and produce the same yield only if a rather special relationship exists between the degree of progression and the shape of the marginal-utility schedules. The conditions under which this neglected outcome is possible can be precisely specified if the model is expressed mathematically. For deducing these conditions with the least possible complexity, a special kind of progressive tax is considered, namely one which applies a proportional rate to income in excess of an exemption. The mathematical argument outlined below is designed to determine the conditions under which an increase in the exemption level of such a tax, accompanied by an adjustment in the rate sufficient to ensure equal yield, will cause more work effort. The conditions thus determined will apply without modification to the case being considered in this paper, which is the substitution of a progressive tax of unspecified form for a proportional tax. A substitution of this sort can be interpreted in the terms of the mathematical model as an increase in the exemption level from zero to some positive number, and the result which holds true for the flat-rate tax with the positive exemption will also hold true for a progressive tax of any form which imposes at the new equilibrium level of income the same average and marginal rates.<sup>1</sup>

Let  $U(y, s)$  be a utility function of disposable income  $y$  and leisure  $s$ , which is twice differentiable. To simplify the analysis we assume that the utility function is additive, that is, the marginal utility of income is assumed to be independent of leisure and vice versa.<sup>2</sup> If  $w$  is the wage rate,  $k$  the total time

<sup>1</sup> An analogous geometrical statement would be that any progressive tax giving rise to a wage-line which passed through  $R$  with the same slope as that of the wage-line  $APQ$  at  $R$  would lead to the same equilibrium as that reached under the tax giving rise to the wage-line  $APQ$ .

<sup>2</sup> Additivity is also assumed in the geometrical statement above. Most of the theoretical conclusions that have been obtained for the effect of taxation on work effort have been based on cardinal utility or the even more restrictive case of additive utility. For example, Musgrave implicitly assumes additivity throughout his discussion, while Cooper develops a proposition for the effect of a proportional tax on work effort which depends only on ordinal properties

endowment, and  $e$  the exemption level, taxable income  $x$  is given by

$$(1) \quad x = w(k - s) - e$$

where it is assumed that gross income exceeds the exemption level. Then disposable income is given by

$$(2) \quad (y = 1 - t)x + e$$

where  $t$  is the tax rate. The first-order condition for a maximum is

$$(3) \quad \frac{U_s}{U_y} = (1 - t)w.$$

The *ex post* equal-yield constraint is given by

$$(4) \quad tx = m$$

where  $m$  is the desired yield. To determine the effect of a change in the tax schedule, we differentiate equations (2), (3), and (4) with respect to  $e$  to obtain

$$(5) \quad \frac{dy}{de} + (1 - t)w \frac{ds}{de} + \frac{dt}{de} = t$$

$$(6) \quad -(1 - t)wU_{yy} \frac{dy}{de} + U_{ss} \frac{ds}{de} + wU_{sy} \frac{dt}{de} = 0$$

$$(7) \quad -tw \frac{ds}{de} + x \frac{dt}{de} = t.$$

From (7),

$$(8) \quad \frac{dt}{de} = \frac{t}{x} \left[ 1 + w \frac{ds}{de} \right].$$

Subtracting (7) from (5),

$$(9) \quad \frac{dy}{de} = -w \frac{ds}{de}.$$

Substituting in (6) and simplifying, we obtain

$$(10) \quad \frac{ds}{de} = - \frac{1}{w + \frac{y - e}{t} \left( \frac{wU_{yy}}{U_y} + \frac{U_{ss}}{U_s} \right)}.$$

---

of the utility function but obtains a conveniently expressible result only in the case in which additivity is assumed. See Musgrave, *op. cit.*, pp. 232-38 and G. Cooper, "Taxation and Incentive in Mobilization," *Quart. Jour. Econ.*, Feb. 1952, 66, 43-66, reprinted in Musgrave and Shoup, *loc. cit.*, pp. 470-92.

Thus  $\frac{ds}{de} < 0$  and more hours of work are induced when the exemption is raised if

$$(11) \quad w + \frac{y - e}{t} \left[ w \frac{U_{yy}}{U_y} + \frac{U_{yy}}{U_s} \right] > 0.$$

In the case under consideration, the initial exemption level is zero so that this condition may be written

$$(12) \quad \eta_y + \frac{y}{ws} \eta_s < t$$

where  $\eta_y$  and  $\eta_s$  are written in place of  $-y \frac{U_{yy}}{U_y}$  and  $-s \frac{U_{ss}}{U_s}$  and are the

elasticities (multiplied by  $-1$ ) of the marginal utility of income and the marginal utility of leisure schedules respectively. The replacement of a proportional tax by a progressive tax with lower average and marginal rates can therefore induce more work effort and produce the same yield if the sum of (a) the elasticity of the marginal utility of income, and (b) the elasticity of the marginal utility of leisure multiplied by the factor  $y/ws$ , is less than the rate of the proportional tax.

## V

The circumstances which give rise to this neglected result are of doubtful realism but they do fall within the assumptions of the standard theorem concerning progression and leisure. For all practical purposes the theorem remains valid, although for accuracy's sake we should qualify its conclusion in this way: if the marginal utilities of income and of leisure both decline, the substitution of an *ex post* equal-yield progressive tax on work income for a proportional tax will cause the taxpayer to reduce work effort, *except that when the marginal utilities decline slowly, a mildly progressive tax with rates substantially lower than that of the proportional tax may produce an equal yield as a result of inducing more work effort.*

## Foreign Exchange Earnings and Price Stabilization Schemes

Whether price and output stabilization schemes for primary commodities are likely to increase or decrease foreign exchange earnings from what they would be otherwise is a question of great importance to the countries contemplating the formation of such institutional arrangements. This paper sheds some light on this question and clarifies under what circumstances Ragnar Nurkse's assertion<sup>1</sup> is valid that countries will fail to maximize foreign exchange earnings if they do stabilize prices.

The analysis abstracts from other benefits that underdeveloped countries can allegedly be expected to derive from a stabilization of world primary commodity prices, such as, for instance, increased long-run demand for these products from the industrial countries, on the grounds that stable prices would remove one of the incentives for finding substitute and synthetic materials. This conclusion follows from the idea that manufacturers often prefer a raw material with a stable price over a raw material with similar physical qualities that has a highly fluctuating price, even if that price may turn out to be somewhat lower over the long run.

On the supply side and benefiting underdeveloped countries more directly, stable product prices and demand make it possible to plan agricultural, mining, and industrial outputs so that average cost per unit of output would be at a technical minimum. Another benefit of stable prices of primary products may be more stable foreign exchange earnings which in turn would facilitate long-run development planning and the importation of capital goods. (See [5, pp. 139-276].)

However, if Nurkse's suggestion is correct and price stabilization schemes would tend to reduce over-all foreign exchange earnings, this effect could outweigh all of the other potential benefits and would thus make altogether undesirable the institution of such schemes.

### I. *The Model*

For purposes of exposition the following assumptions are made: The material is produced only in underdeveloped countries and requires no input costing foreign exchange. Production is responsive to domestic price as indicated by the supply curve shown in Figure 1, which does not shift throughout the length of the business cycle. The specific shape or position of the supply curve is of no importance at this point of the analysis as long as it has neither a zero nor a negative slope. The business cycle in the industrialized countries consists of two periods of equal length, a depression period during which the demand curve looks like  $D_1D_1$  and a boom period with a demand curve  $D_2D_2$ , parallel above  $D_1D_1$ . Domestic frictional costs

<sup>1</sup> "Stabilizing the prices received by producers interferes with the incentive to produce more when export prices are high, and serves perversely to keep up production for export when export prices are low. This is obviously not a pattern that maximizes the producing country's export proceeds over the business cycle" [2, p. 149].

of adjusting output from period to period, i.e., external diseconomies not reflected in the supply curve itself, are zero. It is clear that these assumptions imply that variations in demand are responsible for existing price fluctuations.<sup>2</sup> It is also implied that futures markets and storage of the product are insufficient to offset these cyclical variations in demand. Whatever the size of these equilibrating forces, their influence is assumed to be reflected in the shape of the supply curve or demand curve.<sup>3</sup>

In the framework of this model total foreign exchange earnings without stabilization schemes over the full cycle are equal to  $(OA \cdot OK) + (OC \cdot OM)$ .

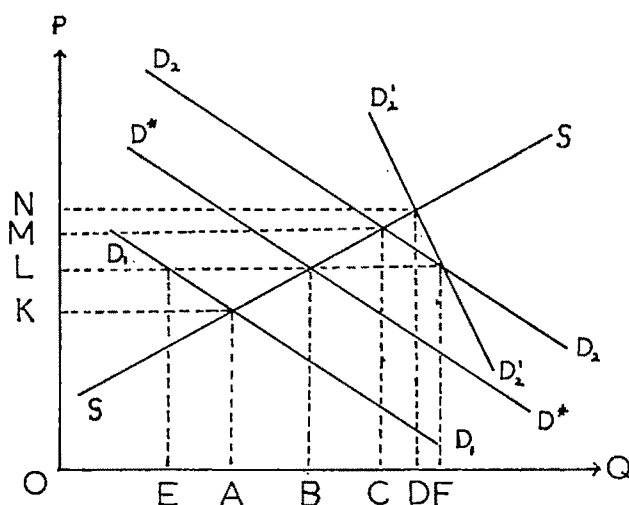

FIGURE 1

The basic question of this paper can now be reformulated to the following: Does the introduction of a stabilization scheme increase or decrease the full-cycle export earnings equivalent to  $(OA \cdot OK) + (OC \cdot OM)$ ? As is intuitively obvious, the answer to this question depends on what type of stabilization scheme is chosen and what the elasticities of the demand and supply functions are. In the following the buffer-stock and buffer-fund schemes will be examined and a brief reference to two other types of funds will be made.

## II. Buffer Stocks

Under this scheme the stabilization board acts essentially as a storage agent. It is assumed to make no profits, to accumulate stocks during depres-

<sup>2</sup> An analysis of export proceeds of primary producing countries during 1901-51 made by the United Nations [4] shows frequent parallel movements of export prices and export quantities. This reflects the dominant influence of demand conditions. J. D. Coppock also found substantial correlation between export quantity and proceeds [1, p. 143].

<sup>3</sup> Since this paper was written, an article has been published which uses much the same basic model but explores the implications which variable home demand and backward sloping supply curves have on foreign exchange earnings when prices are allowed to fluctuate and when a buffer-fund scheme is employed [3].

sion, and to decumulate them during booms. It sets an equal price for both users and suppliers and maintains it from period to period. These conditions mean that the sum of the quantities demanded during boom and depression must be equal to output at that price over the entire time interval. The demand schedule  $D^*D^*$  in Figure 1 shows the average quantity demanded at each price per half of the cycle. The condition that demand should equal supply over the entire cycle is met at a price  $OL$ . At this price output in the first period is  $OB$ , of which  $OE$  is sold and  $EB$  is stored. Second-period demand at price  $OL$  is  $OF$ , which exceeds production  $OB$  by the amount  $BF$ . Since  $BF$  is equal to  $EB$ , the amount stored in the first period is just equal to meet the excess demanded in the second and the net accumulation of stock over the cycle is zero.

Total foreign revenue at the price  $OL$  is equal to  $2(OL \cdot OB)$  and the relevant comparison is whether this quantity is equal to, smaller, or greater than  $(OA \cdot OK) + (OC \cdot OM)$ . The general mathematical formulation of these conditions is complicated even under the assumption of linear schedules, and depends on the elasticities of the functions.

By the use of the diagram, however, it is possible to show the properties of a special case from which some interesting generalizations can be made. Assume that the boom and depression demand curves in Figure 1 shift parallelly. Now it is true that during one period the increase in revenue from the buffer-stock scheme is equal to the area  $(OB \cdot OL) - (OA \cdot OK)$ , i.e., the two strips making up the area  $ABKL$ . Analogously the loss in revenue during the second period is represented by the area  $BCLM$ . But it is true that  $ABKL$  is smaller than  $BCLM$  because, on the basis of the assumptions and the shape of the schedules,  $AB = BC$  and  $KL = LM$ , so that the widths of the strips are equal but, as the diagram shows clearly, their lengths and heights differ. Thus under the given assumptions the increase of revenue in one period fails to compensate for the decrease during the second period so that the buffer stock always reduces foreign exchange earnings below what they would be if the unrestricted market were allowed to function.<sup>4</sup>

<sup>4</sup> The following algebraic proof of this theorem is due to A. C. Harberger.

$$(1) \quad q = a_1 + bp \quad \text{demand schedule during depressions}$$

$$(2) \quad q = a_2 + bp \quad \text{demand schedule during boom}$$

$$(3) \quad q = c + fp \quad \text{supply schedule}$$

$$(4a) \quad c + fp_1 = a_1 + bp_1 \quad p_1 = \frac{a_1 - c}{f - b}$$

$$(4b) \quad c + fp_2 = a_2 + bp_2 \quad p_2 = \frac{a_2 - c}{f - b}$$

$$(4c) \quad c + fp = \frac{a_1 + a_2}{2} + bp \quad p = \frac{\frac{a_1 + a_2}{2} - c}{f - b}$$

But

$$(5) \quad \frac{p_1 + p_2}{2} = \left( \frac{a_1 - c}{f - b} + \frac{a_2 - c}{f - b} \right) / 2 = \frac{\frac{a_1 + a_2}{2} - c}{f - b}.$$

This conclusion confirms the validity of Nurkse's proposition for the case of a parallel shift in the demand curve [2, p. 249]. Nurkse in his paper, however, concentrated on the supply side of the problem and failed to investigate what happens when the assumption of a parallel shift in demand is abandoned. The alternative boom demand schedule  $D_1'D_2'$  drawn in the diagram shows that the amount by which revenue changes as a result of the introduction of a buffer-stock scheme depends on the slope of the demand schedules. Thus by the way in which  $D_1'D_2'$  has been drawn, the buffer-stock revenue would be unchanged because the new  $D_1'D_2'$  curve (not shown) coincides with the old one at the critical price  $OL$ . But under the unrestricted market system boom-period revenue would be  $(OD \cdot ON)$ , which is greater than  $(OC \cdot OM)$ , while the depression revenue remained unchanged at  $(OA \cdot OK)$ . By analogous reasoning it follows that flatter  $D_1'D_2'$  schedules will reduce boom-period revenue from what it is under the parallel-shift case. In fact, a sufficiently elastic  $D_1'D_2'$  curve can lead to an excess of buffer-stock revenues over unrestricted market revenues.

Using the technique just developed and starting again from the case of parallel schedules, it is easy to see that changes in the slope of the depression demand curve have effects opposite from those experienced by changes in the same direction of the slope of the boom demand curve. More inelastic (elastic) depression schedules yield smaller (larger) depression revenues without altering boom or buffer-stock revenues if the  $D_1D_2$  curve is rotated around the price  $OL$ .

How do different supply schedules influence the conclusions reached so far? The method used to show that the introduction of a buffer-stock scheme will always reduce foreign exchange earnings in the case of parallel shifts in the demand curves is valid for any positive slope of the supply curve. However, the exact size of the reduction is dependent upon the slope. Perfectly horizontal and vertical supply curves are the limiting cases where the introduction of the buffer-stock scheme will cause no changes in foreign exchange revenues. For the sake of completeness it is worth mentioning also that a negatively sloped supply curve, given parallel shifts in the demand curves, causes buffer-stock revenues always to be greater than un-

Therefore,

$$(6) \quad \frac{p_1 + p_2}{2} = p, \quad \text{from which it follows that}$$

$$(7a) \quad p_1 = p + \Delta p$$

$$(7b) \quad p_2 = p - \Delta p.$$

Revenue during each period is equal to  $q$  times the equilibrium prices, i.e., period-one receipts  $[e + f(p + \Delta p)](p + \Delta p)$ , etc., so that the formulation of the revenue question becomes:

$$(8) \quad [e + f(p + \Delta p)](p + \Delta p) + [e + f(p - \Delta p)](p - \Delta p) \leq 2(e + f\bar{p})(p)$$

which reduces to

$$(9) \quad 2f\Delta p^2 \leq 0.$$

$\Delta p^2$  will always be positive. When  $f$  is also positive (i.e., the supply curve slopes upward and to the right), the left side will be larger than the right, which means that buffer-stock revenue will always be smaller than unrestricted market revenue. For the case of negative values of  $f$  (i.e., a backward-sloping supply curve) the conclusion is reversed.

restricted-market revenues. (For proof see the algebraic treatment in the last footnote.)

From a purely logical point of view the conclusion from this model is that the introduction of a buffer-stock scheme may or may not increase foreign exchange earnings from what they are under an unrestricted-market system. While this in itself is a valuable insight, the analysis would be more useful if it were possible to establish whether in the real world boom or depression demand schedules are typically more elastic. Unfortunately, no empirical investigations of this question seem to have been undertaken. From a statistical point of view it is probably possible but difficult because of the paucity of data to distinguish between shifts in demand curves and changes in their slopes. On the theoretical level, however, one reason comes to mind why it is likely that boom schedules are less elastic than depression schedules.

Many of the commodities for which price stabilization schemes are considered serve as factor inputs for firms in industrial countries, and demand for them is derived from the demand for the manufacturing firms' products. When during a period of high demand for this output the price of the factor input rises, firms are usually reluctant to substitute another one because such substitutions typically require changes in production processes which are often accompanied by technical uncertainties and temporary reductions in output. While it is likely that there is always some critical difference in the prices of competing inputs at which the switch is undertaken in spite of these difficulties, the point is here that the critical difference is greater during periods when demand for the firms' output is high than when it is depressed. Such a reluctance to switch to a substitute expresses itself statistically in a more inelastic demand curve for factor inputs during boom and leads to the conclusion that under the assumption of a positively sloped supply curve the introduction of buffer-stock schemes will reduce foreign exchange earnings from their free-market level.

### III. *Buffer Funds*

The basic analytical model developed above can be used to examine the influence of a second type of stabilization scheme. Instead of storing the product and setting a uniform price for both users and suppliers, the agency under this scheme sets a stable price only for the producers and lets the market in each period find a price which equilibrates quantity supplied with the quantity demand. If the stabilization agency is required to make no profit and pay out as much to producers as it receives from buyers over the entire cycle, then the price paid to the producers and the quantity supplied by them are uniquely determined. To see how such a scheme would work, consider Figure 2. The basic assumptions are the same as those underlying the first graph.  $D_1D_1$  and  $D_2D_2$  are depression and boom demand schedules,  $SS$  is the supply curve. The locus of points an equal vertical distance from the two demand curves is shown as  $D^*D^*$ . Where this schedule intersects the supply curve, the conditions are met that the agency's excess revenue during boom is exactly offset by the

deficient revenue during depression, and the total earnings over the cycle are equal to the value paid to producers. At price  $OL$  quantity  $OB$  will be produced in each period. The price to users will be established at  $OJ$  during the depression period and  $OQ$  during the boom period, yielding a revenue over the entire cycle of  $(OB \cdot OJ) + (OB \cdot OQ) = 2(OB \cdot OL)$ .

The problem of what happens to total foreign exchange earnings as a result of the introduction of the price stabilization scheme in terms of this diagram comes down to the question of comparing the areas of three rectangles. Is  $(OA \cdot OK) + (OC \cdot OM) \lesseqgtr 2(OB \cdot OL)$ ? For the case of parallel demand curves the conclusions arrived at for the buffer-stock scheme are equally applicable to this scheme because the geometric properties of the

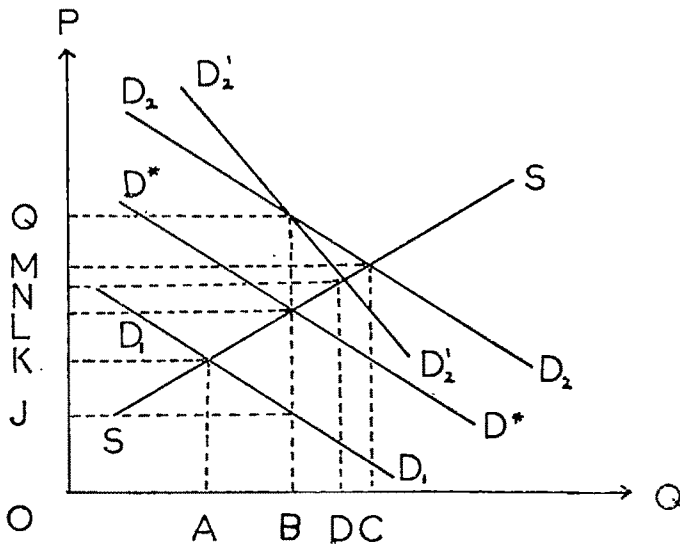

FIGURE 2

functions again are such that the relevant comparison is of the strips  $ABKL$  and  $BCLM$ . Thus the introduction of a buffer fund will always reduce foreign exchange earnings. However, different slopes of the boom demand schedule will have opposite effects from those encountered under the buffer-stock scheme. As can be seen from  $D_2'D_2'$  in Figure 2, a boom schedule less elastic than a depression schedule *reduces* the excess of free-market revenue from what it was under the parallel-shift case. In general the steeper the boom demand curve, the greater the likelihood that the buffer-fund scheme will increase foreign exchange earnings above their free-market level.

The influence which different combinations of the two demand and the supply schedules have on total revenue can be discovered by reasoning in the same way as for the buffer-stock scheme. This analysis is not presented here. The conclusion from such an exercise is again that as a matter of logic

alone the introduction of buffer-fund schemes can either raise or lower foreign exchange earnings. If, however, it is assumed that the boom-schedule is less elastic than the depression schedule and that the supply curve is positively sloped, then it follows that buffer-fund schemes are likely to lead to higher and not, as in the case with the buffer-stock scheme, to lower foreign exchange earnings.

#### IV. *Other Marketing Schemes*

Space limitations make it impossible to explore in detail the application of the basic model to schemes under which the authority is not expected to break even but where instead it seeks to pursue other objectives such as the maximization of foreign exchange earnings or the optimum exploration of its monopoly position. Suffice it to indicate briefly that the first maximization principle requires setting price and output at the points of unitary elasticity on the two demand curves. While such a scheme guarantees maximum foreign exchange earnings, the supply-curve elasticity determines whether the quantities sold can be obtained from domestic producers at an average price greater or smaller than that at which it is sold in the outside world. Thus it depends on the supply elasticity whether the scheme can be used as a taxation device or whether it requires a subsidy.

The second objective leads to a choice of output and prices on the basis of the marginal-cost-equals-marginal-revenue principle. The agency's behavior under the scheme parallels that of a monopolist discriminating in two markets. While this scheme will always improve the terms of trade for the sellers of the product, total foreign exchange earnings may increase or decrease, and simple generalizations about necessary conditions for a specific outcome cannot be made.

#### V. *Conclusions*

The model just presented could be modified to take account of such real world phenomena as typically longer recovery than depression periods of business cycles, storage costs, shifts in demand curves in response to monopoly pricing, etc. It is not likely, however, that the most general conclusion that can be drawn from this analysis would be changed. This conclusion is that the introduction of world primary commodity stabilization schemes does not necessarily increase total foreign exchange earnings accruing to the producing countries.

By introducing assumptions that are in addition to those underlying the basic model itself, it is possible to draw more specific conclusions. If demand is typically less elastic during periods of high demand than it is during periods of depression, buffer-stock schemes are likely to decrease foreign exchange earnings below what they would have been in the absence of such schemes because stable prices over the cycle forego the opportunity to exploit the inelasticity of demand during boom periods. Under these circumstances buffer-stock schemes therefore lead to a conflict between the stabilization and earnings-maximization objectives pursued by government agencies.

Given the same demand conditions, however, buffer-fund schemes do

not present such a conflict between objectives because they allow foreign prices to fluctuate and exploit the inelasticity of boom demand schedules.

### Fluctuations in Economic Activity: Planned and Free-Market Economies, 1950-60

Three of the many claims to superiority made for planned economies over free-market economies stand out clearly: first, that they grow faster; second, that they provide full employment; and, third, that they are not subject to fluctuations in outputs [12, pp. 95-102] [23, pp. 19-35]. The first claim has been discussed at some length in Western literature. Independent indexes of growth for the planned economies have been developed by Western scholars, and the results have been analyzed and compared with similar indexes for the free-market economies [1] [11]. Considerably less attention has been paid to the second claim, possibly because measuring the degree to which the two systems utilize available inputs is an even more complex problem than the calculation of growth indexes.<sup>1</sup> Little attention has been devoted to the third claim<sup>2</sup> that "Socialism is characterized, above all, by the absence of cyclical disturbances in production" [14, p. 9]; no statistical comparisons of fluctuations in economic activity in the two systems are available.

The purpose of this paper is to compare the year-to-year fluctuations in output for a group of planned and a group of free-market economies. The first section describes the scope of the project and the data used, the second presents the results, and the third comments on the findings.

<sup>1</sup> The possibility of underutilization of inputs in planned economies has been pointed out, among others, by Joseph Berliner [2, pp. 358, 363-66], Emily Brown [3, pp. 181-82], Robert Campbell [4], Naum Jasny [9], Alec Nove [15, p. 579], Alfred Oxenfeldt [21], and Lazar Volin [35, p. 306].

<sup>2</sup> Fluctuations in the Soviet Union are discussed by Naum Jasny [10, pp. 11-13], G. W. Nutter [18, pp. 204, 221], and Eugene Zaleski [36, pp. 264-83].

I. *Scope and Methods*

We define as planned economies those whose means of production are owned predominantly by the State and whose economic activities are directed pursuant to an over-all economic plan. The countries for which information is readily available belong to the European Communist bloc: Bulgaria, Czechoslovakia, East Germany, Hungary, Poland, Rumania, the Soviet Union, and Yugoslavia.<sup>3</sup> The free-market countries are the members of the Organization for Economic Co-operation and Development: Austria, Belgium, Canada, Denmark, France, the Federal Republic of Germany, Greece, Iceland, Ireland, Italy, Luxemburg, the Netherlands, Norway, Portugal, Sweden, Turkey, the United Kingdom, and the United States.<sup>4</sup> Neither group is homogeneous. In each there prevail significant differences in per capita income. The approaches to problems of integral planning vary from country to country within the Communist bloc as much as the degree of government intervention varies within the free-market group. Yet a sharp distinction can be drawn between the two on the basis of the institutional framework within which their economies operate, and meaningful comparisons can be made.

The investigation covers 11 years, 1950-60. The recovery years immediately following World War II are excluded as unreflective of normal "peacetime" differences in the performance of the two systems. By 1950 outputs in practically all the countries studied had either reached or surpassed the prewar level. And the basic institutional changes in the Communist bloc had been completed; all these economies were operating on long-term plans.

Variations in volume of four output aggregates are investigated: total output, output in agriculture, in industry (composed of mining, manufacturing, and utilities), and in construction. Since there is no unique way to measure these fluctuations, several methods were tested. They all led to essentially the same results. The results of two methods are presented.<sup>5</sup> The first measure is the standard error of the least-squares fit of the series  $Y_t/Y_{t-1}$  to time, where  $Y$  stands for the value of the variable in constant monetary units and  $t$  stands for time; it expresses the fluctuations in percentage points measured from the trend-line fit to yearly growth rates. The second measure is the antilog of the square root of logarithmic variance of the series  $Y_t/Y_{t-1}$ , with unity subtracted from the antilog.<sup>6</sup>

<sup>3</sup> The first seven countries form the COMECON. No data were available on Albania.

<sup>4</sup> Adequate data were not available for Spain and Switzerland.

<sup>5</sup> Other measures of fluctuations tested were: (1) Pearson's coefficient of variation; (2) the standard error of the least-squares fit to the index of growth with 1950 as the base year; and (3) the standard error of the least-squares fit to the logarithms of index of growth with 1950 as the base year.

<sup>6</sup> For a discussion of the second method, see [5, pp. 23-24]. The formula is:

$$\text{Fluctuation} = \text{antilog} \sqrt{\frac{\sum \left[ \log (Y_t/Y_{t-1}) - \frac{1}{N} \sum \log (Y_t/Y_{t-1}) \right]^2}{N}} - 1,$$

where  $Y_t$  stands for the value of the variable in constant monetary units,  $t$  stands for time, and  $N$  for the number of years minus one.

Data for planned economies were obtained from official statistics released by the central statistical offices of each country. Practically all information on free-market economies was obtained from OECD publications.<sup>7</sup> Two objections might be raised to these data. The first is that the official statistics for growth of output in planned economies suffer from an upward bias. This bias in the trend should not, however, distort the variations around the trend.

The second, more troublesome, objection is that the aggregates studied are not strictly comparable. Most data for all four aggregates in the free-market group refer to gross domestic product at factor cost.<sup>8</sup> For the planned economies, data on total output refer to income originating in material production exclusive of depreciation. In an attempt to make the two sets of data more nearly comparable,<sup>9</sup> two alternative series were used for the free-market economies. First, the part of domestic product originating in the services sectors was omitted.<sup>10</sup> This adjustment probably overcompensates for exclusion of services in planned economies. As Alec Nove points out [16, pp. 253-54], national income of planned economies is built up from the production side by subtraction of material expenditures from total value of their output. Consequently, services rendered to productive enterprises find their way into the "material" national income. Therefore, calculations were also made for the free economies using the official concept of domestic product at factor cost. Lack of data makes impossible any adjustment for depreciation charges, which are excluded from total output in planned but not in free-market statistics. This shortcoming should not, however, greatly affect the comparability of fluctuations. Depreciation charges are small compared to national income in the planned economies,<sup>11</sup> and consequently their exclusion could not increase significantly the measured degree of instability even if we make the extreme assumption that their growth rate was constant.

Unfortunately, no adjustments are possible to make the concepts of agricultural, industrial, and construction outputs more nearly comparable. The boundaries of productive activity in these sectors are not identical in the two groups of economies.<sup>12</sup> More importantly, the data for these three sectors in

<sup>7</sup> Data for the United States are from the Department of Commerce.

<sup>8</sup> In the case of Ireland, Luxemburg, the Netherlands, Portugal, Sweden, and the United States, outputs of the respective industries are represented by the official industrial production indexes; output of construction is represented for each country by the "residential construction" and "other construction" components of the gross domestic fixed capital formation.

<sup>9</sup> For a discussion of an attempt by the Russian economist, Kolganov, to adjust the United States national income to Soviet definition, see [17].

<sup>10</sup> The following sectors compose the gross domestic material product at factor cost: agriculture, forestry, and fishing; mining and quarrying; manufacturing; electricity, gas and water works; construction; transportation and communication; wholesale and retail trade. Excluded are: banking, insurance, and real estate; ownership of dwellings; public administration and defense; health and education services; and miscellaneous services [19, XXXVII].

<sup>11</sup> In Poland, for example, depreciation amounted to about 8 per cent of national income [8, p. 58].

<sup>12</sup> For example, logging and fisheries are included in industry in the Soviet Union. In

planned economies are the familiar gross values of output, which include large amounts of double-counting.<sup>13</sup> Only for three of the eight planned economies are data on income originating in these three sectors available. The income-originating aggregates exhibit larger fluctuations than the gross value aggregates in all but one of the nine cases.<sup>14</sup> Since the concept of income originating is closer to gross product at factor cost, used in the free-market economies, it is likely that the subsequent use of gross value of output data for the planned group somewhat underestimates the degree of their fluctuations.

The limitations of the available information should not be overemphasized. More uniform and detailed data<sup>15</sup> would of course make the comparisons more precise. I am convinced, however, that the conclusions presented in the next section would not be altered.

## II. *The Results*

Table I presents the fluctuations for the individual countries composing the two groups. There is considerable variation in degree of fluctuation both within and between the groups. The path of growth was quite smooth in some countries (Poland, the Soviet Union; France, Italy, Norway), while in other countries it fluctuated widely (Bulgaria, Yugoslavia; Greece, Turkey, the United States). Considering both groups together, the lowest fluctuation in total output occurred in the Soviet Union and in Norway, the highest in Yugoslavia and, to a lesser degree, in Turkey. The output of agriculture fluctuated little in Poland, Czechoslovakia, Luxemburg, Sweden, and the United States; widely in Yugoslavia and Canada. Industrial output of the Soviet Union grew more smoothly than that of any other country considered; the United States registered the highest fluctuations. The growth of construction was smooth in the Soviet Union, in France, and in the United Kingdom; it varied greatly in Bulgaria, Rumania, and Turkey.

The performance of the Soviet Union is of particular interest not only for the obvious reason that it is the most powerful nation of the Communist bloc, but also because it is the one with most experience in economic planning. Except for agriculture, it experienced the lowest fluctuations among the planned economies. Its performance, however, seems to have been duplicated by free-market countries. It was either matched or surpassed by France, Italy, Norway, and Sweden in total output; by Austria, Denmark, France, the Federal Republic of Germany, Luxemburg, Sweden, the United States, and the United Kingdom in agriculture; and by Denmark, France, Italy, and the United Kingdom in construction. Only in industry—the show-window of its

---

Czechoslovakia agricultural output does not include forestry but does include fisheries. Yugoslavia publishes separate series for these three sectors. Definitional differences would of course be important if we attempted to measure, for example, the relative levels of output in the two systems. These differences should not have much influence on fluctuations over time.

<sup>13</sup> Net production constituted in Poland less than one-half of gross production in agriculture, about one-third in industry, and about one-half in construction [8, pp. 58-59].

<sup>14</sup> Fluctuations are about equal in the net and gross output of Czechoslovak industry.

<sup>15</sup> Data for some aggregates are published as three-digit numbers only.

economic growth—does the Soviet Union demonstrate a greater stability in growth than the free-market economies, being followed by France, Sweden, and Turkey.

The results for the two groups are summarized in Table II, which compares their mean fluctuations. Three pairs of averages have been calculated. First, the averages for the eight planned and the 18 free-market economies. Second, since fluctuations in total output might depend on the level of economic development (with agricultural output comprising a large and widely fluctuating share), only those OECD countries are considered which had in the mid-fifties per capita incomes similar to those of the Communist bloc.<sup>18</sup> Finally, four planned economies of Central Europe (Czechoslovakia, East Germany, Hungary, and Poland), which had previously belonged to the economic community of Western Europe but which introduced economic planning after World War II, are compared with the Common Market countries.

In all these comparisons the indicated mean fluctuations were higher in the Communist bloc than the OECD economies for all four aggregates. Only in industry is the mean for the planned economies close to the average for free-market countries.

### III. *Comments*

The findings of this study—that the planned economies of the Communist bloc were subject to fluctuations in economic activity equal to or greater than those experienced by the free-market economies of the OECD—raise four questions. First, was there a difference between the two blocs in the extent to which fluctuations took the form of mere changes in positive growth rather than absolute decline when compared to the preceding year; if a decline, how long did it last? Second, assuming that the eight planned economies considered here in some way represent all planned economies and the 18 free-market economies represent all free-market economies, what statistical significance can be attached to the differences of means in the two groups? Third, may the larger fluctuations of the planned economies have been merely the price paid for an allegedly more rapid increase in output? Fourth, what influence does the particular time period studied have on the results obtained?

1. The percentage of absolute declines in all year-to-year changes amounted in the planned economies to 10.1 for total output, 30.4 for agriculture, 2.5 for industry, and 8.7 for construction. The corresponding figures for the free-market economies are 5.6 for total output, 27.9 for agriculture, 9.5 for industry, and 23.2 for construction. Thus, the free-market economies had fewer interruptions in positive growth of total output and, by a slight margin,

*(See next page for Tables I and II)*

<sup>18</sup> These countries are Austria, the Federal Republic of Germany, Greece, Ireland, Italy, the Netherlands, Portugal, and Turkey. For the planned economies, the range of per capita income is \$177 in Yugoslavia and \$500 in Czechoslovakia. For the free-market economies, the range is \$219 in Turkey and \$508 in the Federal Republic of Germany [27, pp. 69-73].

<sup>a</sup> Decimal moved two places to the right for both methods.

<sup>b</sup> Numbers in parentheses are for the domestic "material" product at factor cost.

<sup>c</sup> Data not available.

<sup>d</sup> Data for East Germany are not available in constant DM. Stolper's figures covering the period 1950-58, expressed in constant 1950 prices, show the following fluctuations (Method 1): income, 2.1; agriculture, 13.2; industry, 3.2; and construction, 14.8 [26, p. 418].

<sup>e</sup> The year 1956 was omitted from the calculation to reduce the effect the Hungarian Revolution had on the path of growth. Should this year be included, the fluctuations in the four aggregates are as follows (Method 1): income, 10.8; agriculture, 14.3; industry, 9.4; and construction, 15.3.

<sup>f</sup> Gross value data in constant florints are not available; data on income originating in construction were used.

<sup>g</sup> Gross value data are not available. Hours worked in construction show the following fluctuation: 16.0 (Method 1), and 11.7 (Method 2).

<sup>h</sup> The period for agricultural output is 1952/53-1960/61.

<sup>i</sup> The period covered is 1952-59.

<sup>b</sup> Austria, the Federal Republic of Germany, Greece, Ireland, Italy, the Netherlands, Portugal, and Turkey; these Western countries were classified by Studenski [27, pp. 67-70] together with the Communist bloc countries in the Middle-Income Group.

<sup>c</sup> Czechoslovakia, East Germany, Hungary, and Poland.

<sup>d</sup> Belgium, the Federal Republic of Germany, France, Italy, Luxembourg, and the Netherlands.

*Sources:* Table I.

of agriculture, while planned economies showed fewer lapses from positive growth in industry and construction. Typically, all decreases lasted for only one year in both groups, though in several free-market countries agriculture and construction outputs declined in two consecutive years.

2. If the fluctuations experienced by the two groups are normally distributed and independent, we can test for statistical inference our finding that the mean fluctuations of each aggregate were higher for the first than the second group. The results of the test are shown in Table III. The variances of total outputs in the two groups are too different to permit the *t*-test.<sup>17</sup> For the other three aggregates, the mean fluctuation is significantly higher in planned economies in agriculture and construction, but not in industry.

3. The degree of association between fluctuations and growth rates can be expressed by the correlation coefficient between the two variables. Considering both groups together, the coefficient for total output is  $+0.15$  and is not significant. A significant relationship exists in agriculture where the coefficient is  $+0.53$  and in construction where it is  $+0.45$ ; the first one is significant at 1 per cent level, the second one at 5 per cent level. In industry, a surprisingly negative (though not significant) relationship exists between the two variables; the coefficient is  $-0.25$ . Thus no consistent pattern is apparent between fluctuations and rate of growth.

4. The period under study is the only one for which comparisons between a number of planned and free-market economies can be made. Only the future will show how "unrepresentative" the decade of the 'fifties might have been for the planned economies or for the free-market group. The experiment of integral planning was new for all countries of the Communist bloc except the Soviet Union, and, with the exception of agriculture, the Soviet Union experienced the lowest fluctuations. As more planning expertise is acquired and perhaps more institutional stability achieved, these countries will probably reduce fluctuations in their economic activity. The free-market economies may, on the other hand, find their era of relatively stable growth coming to an end. We can state with reasonable certainty, however, that unless the performance of the free-market countries deteriorates substantially, the planned economies have some considerable way to go before they can substantiate the claim of superiority with respect to fluctuations. Should the bloc countries be unsuccessful in dampening their output fluctuations experienced in the last decade, a "cycle theory" will perhaps have to be advanced for this new type of economic organization. The explanation would presumably run in terms of such factors as rapid shifts in economic policies, changes in

<sup>17</sup> Perhaps it should be pointed out here that a significant value of *t* is not due to the lack of equality of the two variances. The variance for planned economies is larger in all instances, i.e., as far as fluctuations are concerned, there was less homogeneity in planned than free-market group. However, if claims such as "planned economies grow faster" are advanced, the difference in fluctuations variances does not impair the comparability of the two groups. It would be difficult, for example, to accept planning as the cause of more rapid growth but ascribe the fluctuations in growth to another cause.

TABLE III—DIFFERENCE OF MEANS IN FLUCTUATIONS: PLANNED AND FREE-MARKET ECONOMIES, 1950-60

### The Effectiveness of "The American Economy" in Training Secondary School Teachers

As part of a major national effort to aid secondary schools in improving economic instruction at the high school level, the American Economic Association joined with the National Task Force on Economic Education, the Joint Council on Economic Education, and Learning Resources Institute in sponsoring a nationwide television course entitled "The American Economy" during the 1962-63 academic year. Professor John R. Coleman of Carnegie Institute of Technology served as the national teacher for the television course, and a large group of distinguished economists from universities, business, labor, and agriculture served as consultants and visiting lecturers.<sup>1</sup> A major goal of the course was to teach more economics to high school social studies teachers.

"The American Economy" has now completed its run on some 182 CBS television stations and an additional 54 educational and 5 independent television stations throughout the country. The estimated audience of regular viewers for this 160-lesson series (128 lessons on economic content and 32 lessons on teaching methods) was over 1 million persons, including some 5,500 persons who took the course for college credit at one of the 361 colleges and universities across the land which offered credit for "The American Economy."

Apparently most of the 5,500 persons taking the course for credit were school teachers. Since there are presently some 61,000 secondary social studies teachers in the United States, this is just a beginning. But it is a significant beginning. Most educational television stations will run the series again during the 1963-64 academic year, and the entire course of the 160 lessons is now available on movie films that can be shown on any standard 16 mm. sound projector. This makes "The American Economy" available as a basic resource for in-service teacher training programs and summer workshops for secondary school teachers, as well as others, for some years to come.<sup>2</sup>

How effective was the national TV course in teaching high school teachers? The National Opinion Research Center has been engaged to do a thorough evaluation, using a standardized test with appropriate control groups along lines recommended by the National Task Force on Economic Education. This paper reports the results of an earlier, similar, though smaller, study in the Pittsburgh area. These results indicate that the TV course was successful

<sup>1</sup>For a complete listing of the lesson topics and guest lecturers, see [2]. Professor Coleman also discussed the course in [1].

<sup>2</sup>The film series may be used either in its entirety or in one of several alternative analytical subdivisions prepared by Professor Coleman. Details on rental or purchase arrangements for these films can be obtained through the National Education Television Film Service at the Indiana State University Audio-Visual Center, Bloomington, Indiana.

in improving teachers' knowledge of the fundamental economic concepts outlined in the 1961 report of the National Task Force on Economic Education as "the minimum understanding of economics essential for good citizenship and attainable by high school students" [3, p. 4].

The background of the television course in the Pittsburgh area will be presented. The testing instrument and the testing procedure used in the study will be discussed, and the results will be analyzed, using both simple correlation and multiple regression techniques. Some concluding observations and suggestions for further research will complete the paper.

### *I. Background of the TV Course in Pittsburgh*

"The American Economy" was broadcast three times daily over Pittsburgh television stations. Seventy-one high school and junior high school teachers in Allegheny County took the course for graduate credit in education at one or another of the three local Pittsburgh universities—Carnegie Institute of Technology, Duquesne University, or the University of Pittsburgh.<sup>3</sup> Regardless of the university involved, all the students were required to watch the television series thirty minutes each day, Monday through Friday, in addition to meeting at a local university for two hours every other Saturday morning to discuss the economic content lessons with an economics faculty member. The students were divided into three subgroups of approximately 24 persons each for these discussion sessions. Each discussion group met with the same faculty member throughout the entire year.

### *II. The Testing Instrument and the Testing Procedure*

An ideal way to determine the effect of the TV course on these students would have been to administer a standardized test of economic understanding on a before-and-after basis. Unfortunately, such a test was not available at the beginning of the course. During the past year, however, a committee of leading economists, educators, and psychometricians, under the chairmanship of Dr. John M. Stalnaker, President of the National Merit Scholarship Corporation, has been developing a standardized test to measure the basic amount of economic understanding outlined in the National Task Force report cited above.<sup>4</sup> A preliminary form of the Stalnaker Committee's test was available shortly before the completion of the television course, and it was used to measure the economic understanding attained by the TV students and by two other groups selected for "control" purposes.

The test consists of 50 multiple-choice questions, with four possible responses to each question. It has now been administered to some 3,000 high school students and to a smaller number of college economics students and

<sup>3</sup>Thirty-five other persons took "The American Economy" for undergraduate credit at one of the Pittsburgh universities, but these people were not included in the study described in this paper.

<sup>4</sup>The economists on the Stalnaker Committee are G. L. Bach, Carnegie Institute of Technology; Edgar Edwards, Rice University; Joseph Kershaw, RAND and Williams College; Ben Lewis, Oberlin College; and Lewis Wagner, State University of Iowa.

high school teachers. National norms are being established and refinements made so that the test may be available for widespread use during the 1963-64 academic year.<sup>5</sup>

The Stalnaker test was administered to the 71 television students on the next to the last class meeting of the year. The test was also administered to 113 Carnegie Tech sophomore economics students during the last week of their second semester of study; and another group of 73 school teachers, substantially identical to the TV students, but who had not watched "The American Economy," was also selected and tested.

In selecting the teacher control group, one overriding concern was to protect against the possibility that the TV group might be "self-selected" and that they might have a different motivational make-up than another group of randomly selected school teachers. The teacher control group, therefore, was selected in two parts. The first part consisted of another non-TV class in graduate education which met on a night school basis somewhat similar to the TV course. Presumably the 30 persons in this course were motivated to do extra work for graduate credit in education, just as were the TV students. The second part of the control group consisted of 43 Allegheny County school teachers selected at random by the four major school superintendents in the county.

Owing to substantial differences in age, orientation, and training, it was realized that only crude comparisons could be made between the TV students and the college sophomores. In selecting the control group of teachers, however, it was hoped that the influence of the TV course could be identified by using simple correlation and multiple regression analysis to isolate the relationships of several factors which might be presupposed on a priori grounds to have an influence on a respondent's test score.

### III. *The Test Results*

The TV group scored an average of 40.9 correct responses on the 50-item multiple-choice test, with a range of 27 to 50, and a standard deviation of 4.8.

The Carnegie Tech sophomores achieved a mean score of 40.8 correct responses out of 50, with a range of 29 to 48 correct responses, and a standard deviation of 4.2.

The control group scored an average of only 33.9 correct responses on the test, with a range of 21 to 46, and a standard deviation of 5.6.<sup>6</sup>

Thus, those who took either the TV course or the regular college economics course scored substantially higher than the teacher control group. But there was no significant difference between the scores of the teachers who took "The

<sup>5</sup> A revised version of the test is now available through Science Research Associates, 259 East Erie Street, Chicago, Illinois.

<sup>6</sup> There was no significant difference in the mean scores of the two segments of the control group. The graduate-education class obtained a mean score of 32.3 out of 50, and the teachers selected by the county superintendents obtained a mean score of 35.0, but this difference could have occurred by chance three times out of four.

American Economy" for credit and the college sophomores on this very basic test of economic knowledge.<sup>7</sup>

The seven-point difference between the mean scores of the TV students and the teacher control group can be interpreted as a 14 per cent improvement on a 50-item test, or it can be interpreted as a 20.6 per cent improvement over the base of 33.9 scored by the teacher control group, or it can be viewed as an increase of 43.5 per cent of the distance between the control group score and the perfect score of 50. In any case, it would appear that the teachers who took "The American Economy" in the Pittsburgh area knew substantially more economics at the end of the course than did a similar group which did not take the course. The question which remains is how significant is the TV course in explaining this difference when compared to other factors that might have influenced either the TV group or the control group.

#### *IV. Analysis of the Results*

In order to answer this question, data were collected from each respondent in the TV group and from each respondent in the control group on several variables which might be assumed on a priori grounds to have an influence on a respondent's test score. Then a simple correlation and a multiple regression analysis were conducted in an attempt to isolate the influence of the TV course itself. For each respondent, information was obtained on: taking the TV course for credit ( $X_1$ ), age ( $X_2$ ), sex ( $X_3$ ), teaching experience ( $X_4$ ), educational background ( $X_5$ ), and a measure of the respondent's motivation for advanced education ( $X_6$ ). No direct information was available on the very important question of the respondent's native intelligence, but there is no reason to believe that either group was significantly biased one way or the other on this variable. There was also no information available on how conscientiously the TV students had followed the daily broadcasts.

Various measures were obtained for some of the major variables mentioned above, but in these cases only the most significant measures of each variable will be discussed.

Table 1 shows the simple correlation coefficients between the six independent variables and the Stalnaker test scores of all 144 respondents. Completion of the television course was the variable most positively correlated with the test scores, followed by previous work in college economics, teaching a high school social studies course, chronological age, and male sex in descending order. Motivation for recent college work beyond the bachelor's degree was negatively related to the respondents' test scores.

The positive correlation between age and test performance and the negative correlation between the motivation variable of recent college work beyond the bachelor's degree and the test scores are somewhat surprising, since

<sup>7</sup> These results, of course, do not indicate how the two groups might have scored on a more difficult test, nor do they necessarily indicate that the TV course is an adequate substitute for a regular college course. Much more research will have to be done with more sophisticated measuring instruments and more comprehensive study designs before any firm conclusions can be reached on this point.

one might assume that younger teachers and those actively taking advanced work within the past three years might be more "up-to-date" and perhaps have a better knowledge of basic economic ideas. The small size of the correlation coefficients, however, indicates that these relationships are not likely to be of major importance. Positive or negative, coefficients of .14 and  $-.08$  suggest that neither age nor the motivation to take advanced work had much relation to performance on the Stalnaker test.

Going beyond a simple correlation analysis, a multiple regression model of the linear form  $Y = a + b_1 + b_2 + \dots b_n + u$  was used to assess the importance of each of the independent variables in the presence of the other variables. Here,  $Y$  represents the dependent variable of the test score, the  $b$ 's represent the independent variables described in Table 1, and  $u$  represents a random disturbance term assumed to have the usual simplifying properties. Statistically, this analysis helps to determine the weights to be applied to each of the independent variables in a way that eliminates the possible interrelation of the variables considered in the simple correlation analysis.

Table 2 shows the regression coefficients ( $b$ 's) and the " $t$ " statistics for various combinations of independent variables used in the multiple regression model. The per cent of variance "explained" ( $R^2$ ) for each regression is shown in the right-hand column, and the " $p$ " values required for significance at various confidence levels are shown at the bottom of Table 2.

Regressions one through five run the TV variable and each of the other independent variables in relation with the test score. The TV variable ( $X_1$ ) remains highly stable and highly significant in all of these regressions. Male sex ( $X_3$ ), teaching a high school social studies course ( $X_4$ ), and a previous college course in economics ( $X_6$ ) are all significant at the .005 level when considered separately with the TV variable in explaining the test scores.

TABLE 1—SIMPLE CORRELATION COEFFICIENTS BETWEEN VARIOUS RESPONDENT CHARACTERISTICS AND STALNAKER TEST SCORES

Independent Variables	Simple $r$ With Test Score ( $Y$ )
$X_1$ <u>Television Course</u> (Dichotomous Variable: TV=1, No TV=0)	.56

2. $t$	8.48††		2.69††				
$b$	6.94			2.56			.354
3. $t$	8.15††			2.89††			
$b$	6.89				3.29		.368
4. $t$	8.19††				3.44††		
$b$	7.08					0.16	.315
5. $t$	7.97††					0.17	
$b$	7.10	-0.03	1.16	1.16	2.54	-0.31	.391
6. $t$	8.07††	-0.58	1.18	1.16	2.34***	-0.32	

$t$  values required for significance at various levels of confidence

$t$ value	confidence level
1.29	.10*
1.66	.05**
1.98	.025***
2.67	.005††

Neither the age variable ( $X_2$ ) nor the motivation variable ( $X_6$ ) is significant in relation with the TV variable, but in this analysis the age variable takes on a very small negative coefficient and the motivation variable takes on a small positive coefficient. This reversal of the signs from those in the preceding simple correlation analysis is more in line with what one might expect; but, again, neither of these variables appears significant.

Regression six runs all of the independent variables in the same equation. The TV variable remains significant at the .005 level, and taking a previous college economics course is significant at the .025 level. None of the other variables is significant in this regression. The  $R^2$  of .391 indicates that the six independent variables considered in this analysis leave a large amount of the variation in the test scores unexplained. The purpose of this paper, however, is not to explain all of the variation. Rather, it is to see if the significance of the TV variable holds up after introducing the other variables.

If data on the respondents' intelligence and conscientiousness in watching

the TV course were available, the  $R^2$  could undoubtedly be increased; but, in the absence of such data, taking the TV course remains by far the most significant variable in explaining the differences in the test scores. The coefficient for this variable also remains highly stable in all of the regressions shown in Table 2, as well as in all the other combinations of these variables not shown in this paper.

Since the test used to measure economic understanding in this experiment was a very simple, objective test, and since some of the limitations of this type of testing are well known, one final observation may be useful in interpreting these results. This is simply the fact that regular-course grade information, based entirely on essay exams, was available for both the TV students and the Carnegie Tech sophomores. The Stalnaker test scores of the Carnegie Tech students had a simple correlation coefficient of .70 with their independently determined course average, and the Stalnaker scores of the TV students had a simple correlation coefficient of .82 with their independently determined course grades.

### *V. Conclusion*

This analysis has shown that the teachers taking "The American Economy" television course for graduate credit in education in the Pittsburgh area scored substantially higher on a standardized test of elementary economic understanding than did a similar group of teachers who did not take the television course. In explaining the difference in test scores, the TV course itself proved to be by far the most significant of the six major variables considered. The next most important variable in explaining the difference was previous college work in economics.

How much of the superior performance of the TV students can be attributed to the TV broadcasts themselves and how much attributed to the biweekly follow-up sessions cannot be estimated from these Pittsburgh results, but the forthcoming nationwide study by the National Opinion Research Center will investigate this problem directly.

Pending the results from this more comprehensive study, one may tentatively conclude from the results examined in this paper that the nationwide broadcast of "The American Economy" did contribute significantly to its main purpose of increasing secondary school teachers' grasp of the minimum level of economic understanding outlined in the 1961 report of the National Task Force on Economic Education. No evaluation of the long-range effectiveness of this course is possible, however, until more research is done on what, if any, use is made of this knowledge by the teachers in their own classrooms. With a large number of teachers having recently completed the television course, the opportunity for launching serious research in this area by professional economists willing to cooperate with these people has been increased substantially.

### A Controlled Evaluation of "The American Economy"

During the 1962-63 academic year 27 students at the University of Nebraska took their principles of economics through the CBS-TV college credit course, "The American Economy."<sup>1</sup> These students viewed the half-hour television lectures four days per week, each lecture being followed by 10-15 minutes of questions and answers or elaborating comments by the professor supervising the television course. Students in the television group were all full-time university students rather than public school teachers or casual adult viewers. The lecture group with which the television group was compared was a quite sizable class of 107 students whose program of instruction consisted primarily of three 50-minute lectures per week. Both groups—the television group and the lecture group—used the same textbook and the study guide which accompanies it. The television group also used the television study guide, *The American Economy* [2], while the lecture group did not.

This over-all arrangement afforded a unique opportunity to evaluate through a controlled comparison the relative performance of the television group and the lecture group. The general dearth of scientific investigation in the teaching of economics [3] and the recent interest in economic education seemed compelling reasons for undertaking such an evaluation.

#### I. Testing Techniques and Procedures

The television group and the lecture group were given two multiple-choice examinations totaling 170 questions. The first examination of 120 questions, which we shall refer to hereafter as the Course Examination, was prepared by the authors of this paper. The questions on this examination were of three quite distinct types: factual, conceptual, and problem-analytical. The 20 factual questions were of a "basic data" character: At what average annual rate has the U. S. gross national product increased over a period of years? What is the single most important source of revenue and type of expenditure of the federal government? What is the most important cause of the public debt? Sixty questions were designed to evaluate the student's ability to define or identify basic economic concepts, e.g., the marginal propensity to consume, marginal cost, the multiplier, the short run, price elasticity of de-

<sup>1</sup>The underlying assumptions and character of this course have been summarized by the national teacher. See John R. Coleman [1].

mand, the law of increasing costs. The remaining 40 questions were problems or analytical questions wherein, for example, students were required to interpret graphs, calculate and analyze cost and demand data, compute the elasticity coefficient from demand data, and determine the gains from trade and the terms of trade from comparative cost data. All of the 120 questions were based upon textbook material which was common to both the television and lecture groups.

A brief discussion of the rationale for identifying and employing three types of questions in the Course Examination is in order. Inasmuch as the television course was designed primarily to further general economic understanding rather than to prepare students for more advanced work in economics,<sup>2</sup> it was hypothesized that the lecture group would perform relatively better than the television group on questions that required the mastery of technical economic concepts and their application to the solution of numerical and graphical problems.

The second examination given to the two groups was the Test of Economic Understanding prepared by a distinguished group of economists and educators and published by the Joint Council on Economic Education. It is to be noted that this 50 multiple-choice question examination was designed primarily for high school students who might or might not have had formal coursework in economics. In other words, this examination was not designed to measure achievement after a student had taken a specific course or read certain materials. While the questions contained therein are a mixture of the three types used in the Course Examination, the Test of Economic Understanding is undoubtedly less discriminating at the college level.

Because the cumulative grade averages of the television group and the lecture group were substantially different,<sup>3</sup> the authors decided to make a matched-pairs comparison. Twenty-seven of the 107 students comprising the lecture group were matched to the 27 television students on the basis of three variables: cumulative grade average, number of credit hours of college work completed, and college affiliation (course of study). The mean cumulative grade averages for the matched groups were identical (4.8). The average number of credit hours completed per student was very similar—61.8 hours in the television group and 60.4 hours in the lecture group. College affiliations, while not identical, varied little: each group contained 15 business administration students; the television group contained three engineering students and the lecture group four; etc.

## II. Test Results and Their Significance

The results of the matched-pairs comparison are summarized in Table 1. The television group scored very slightly higher on the Test of Economic

<sup>2</sup>The television lectures on price theory, for example, made no reference to marginal cost and marginal revenue in the determination of output adjustments under different market conditions.

<sup>3</sup>Based on a scale where 9 is the highest and 1 is the lowest grade, the lecture group was found to have a 5.4 cumulative grade average as compared to 4.8 for the television group.

Understanding and the 20 factual questions than did the lecture group. On the other hand, the lecture group performed substantially better on the 60 conceptual and 40 problem-analytical questions than did the television group.

Computation of "*t*" values revealed that the mean differences on the conceptual questions were statistically significant at the 5 per cent level, while on the problem-analytical questions the difference was significant at the 0.1 per cent level. The mean differences on the factual questions and the Test of Economic Understanding were not statistically significant.

A non-parametric test of significance, namely, the Wilcoxon matched-pairs signed-rank test, was also applied to the same data. The results of this second test confirm in each case the findings of the "*t*" test.

### III. Conclusions and Qualifications

What do these comparisons prove? Two conclusions seem warranted upon the basis of this particular evaluation.

1. The performance of the two groups on the Test of Economic Understanding and the factual data component of the Course Examination suggests that "The American Economy" television course was as successful as the lecture course in conveying a broad, general understanding of economics.

2. The lecture group seems to have achieved a higher level of understanding of specific economic concepts and of analytical tools than did the television group. Stated differently, if a firm grasp of economic concepts and the ability to apply the analytical tools of economics to problems and issues are held to be basic goals of the college principles course, "The American Economy" may not have been a perfect substitute for the typical college course. It is relevant to note at this juncture, however, that this second conclusion tends to impose an objective on "The American Economy" that is not entirely consistent with the goals set forth by the national teacher. Although the television course was "assumed to be the equivalent of one year's

TABLE 1—MEAN DIFFERENCES ON EXAMINATIONS AND THEIR STATISTICAL SIGNIFICANCE

work in economics for nonspecialists at a quality college . . . [and covered] the same broad ground found in most of the widely selling economics textbooks," the course was designed primarily for the secondary school social studies teacher and was intended "to go just beyond that minimum degree of economic literacy described in the National Task Force report" [1, p. 646]. In other words, this second conclusion is in no way inconsistent with the proposition that "The American Economy" was highly successful in fulfilling those objectives it set out to achieve.

There are several grounds upon which these conclusions and their significance might be challenged. It is perhaps useful to anticipate and evaluate these possible criticisms [4].

1. A first potential criticism is that the experiment does not embrace certain variables that might reasonably be expected to have a bearing upon the performance of the groups compared. There are two defenses for this criticism which, in our view, substantially diminish its relevance. First, as previously noted, the matched-pairs comparison took cumulative grade average, credit hours completed, and college affiliation into account. While other variables, e.g., outside employment, sex, family background, and type of student housing, might be argued to have some bearing upon the performance of the two groups, it can be countered that the cumulative grade average used in the comparisons can reasonably be expected to reflect these other variables. Second, if these allegedly neglected variables are of crucial importance, the relative homogeneity of the television and lecture groups would seem to constitute a *prima facie* case that such variables would influence the performances of both groups in the same direction.

2. A second criticism might be that this experiment has validity only within the confines of the University of Nebraska. However, the students at Nebraska are probably typical of students in the elementary economics course at a large number of American colleges and universities. Furthermore, there was nothing atypical about the control (lecture) group, and the course was quite standard as to subject matter, type of presentation, textbook and supplementary materials, etc. The class size (107) is undoubtedly less atypical than would have been the case a few years ago. In short, there is reason to believe that a similar experiment at any one of a large number of other institutions would have yielded similar results.

3. Objective examinations were employed in this comparison for two reasons: (a) to avoid the subjective element involved in the scoring of non-objective examinations and (b) to facilitate the sampling of student understanding of a wider range of subject matter. It can be argued that many basic educational goals may be ignored in the measurement of students' grasp of factual information and basic concepts and their ability to manipulate analytical tools through multiple-choice questions. It is true, of course, that the over-all "effectiveness" of any economics course is undoubtedly multidimensional. Which of the two groups acquired a more permanent interest in economics? How have the attitudes of the two groups toward value (policy) positions which they do not share been affected? With what impressions of

the importance of the social sciences as an area of scholarly endeavor have the two groups emerged from their respective courses? The present study admittedly does not shed light on these questions. But lacking empirical evidence, we see no *prima facie* reasons why either of the courses here compared would be of superior effectiveness in achieving these more nebulous goals. It is perhaps relevant here to recall Professor Coleman's comment that "We will have wasted an opportunity and precious resources if we let this [television] series pass without systematic study of its accomplishments and shortcomings" [1, p. 647]. We envision the present report to be only one aspect of this over-all evaluation.

#### The Brown Shoe Case and the New Antimerger Policy: Comment

I should like to offer several comments on the recent Brown Shoe decision [1] which David Martin ably analyzed in the June 1963 issue of this *Review* [3].

1. The Brown decision ostensibly settles one of the thorniest issues in antitrust law: the issue of market definition in merger cases. In holding that relevant submarkets, product and geographic, may exist within the boundaries of the broad market, the Court apparently ruled that the market may be drawn more narrowly in a merger case than in a monopoly case. Unfortunately, the decision is not altogether clear on this point. After stating that submarkets are germane in a Section 7 case, the Court proceeded to argue that the relevant market must be drawn broadly enough to recognize competition where it exists and to correspond to economic reality. Obviously, a market drawn to include competitive products and suppliers traces out the true boundaries of a market, regardless of whether it is termed a broad market or a submarket.

Martin argues, however, that in the Brown case the Court did not accept the Sherman Act guidelines to market definition in merger cases. Since this is

a common interpretation, I shall address my comments to the question of whether the definition of the market should vary with the violation and anti-trust statute. Is it tenable, as several commentators have argued, to exclude substitute suppliers in merger cases under the Clayton Act, even though we include them in monopoly cases under the Sherman Act [7] [4] [2]?

The assumption underlying the submarket approach in merger cases is that the submarket is meaningful in itself, i.e., that the submarket marks off an important area of competition. The difficulty with this assumption is that one cannot determine whether this is true without examining the broader market, the market comprising those firms selling substitute products to a common group of buyers.<sup>1</sup> It is within the broad market, not the submarket, that the stuff of price determination and competitive rivalry is found. If the market definition in a monopoly case excludes some of the firms within this market, we cannot determine whether a defendant has insignificant or substantial monopoly power. If the market definition in merger cases excludes some substitute products or if the market is defined so narrowly that it includes only those firms which happen to be selling in a given area, we cannot reasonably know whether the merger will damage competition; for the submarket approach will restrict us to an examination of only a segment of the market and only a part of the forces which determine price and firm behavioral patterns. The merger of two companies which retail low-priced shoes in the same urban neighborhoods may or may not affect industry leadership, alter price, change competitive tactics, inconvenience buyers or suppliers, or trigger other mergers. And there is no way of knowing such things if we restrict ourselves to a product and geographic submarket.

Rightly or wrongly, the courts have sometimes taken a quantitative approach to merger legality, concentrating entirely on market-share statistics. Even on these terms, the market should not be defined differently in merger than in monopoly cases. Suppose there are two sets of firms, that each set has three firms, that each firm is equal in size, and that the products of set A are competitive with, but differentiated from, the products of set B. If one of the firms in set A acquires the other two firms in its set, the government could challenge the acquisition under either Section 2 of the Sherman Act or Section 7 of the Clayton Act. If substitute products are included, as they presumably would be in a monopoly-power case, the firm has achieved a 50 per cent share of the market; if substitute products are excluded, as the Brown decision implied they could be in a Clayton Act proceeding, the firm has achieved complete monopoly control. But obviously the probable damage to competition is the same regardless of how we define the market. Surely we do not multiply the actual or potential damage of the merger by choosing to prosecute under one law rather than another. Alternatively, if one of the firms in set A acquires two of the firms in set B (rather than set A), the government would not characterize the merger as conglomerate, realizing that this

<sup>1</sup>The broad market may, of course, exclude certain goods which are extremely poor substitutes because of quality or price differences. And some sellers of the relevant product may not be in the relevant geographic market because of transportation costs.

would weaken its case under the Clayton Act and destroy it under the Sherman Act. But this implies that the merger is significant in terms of actual or potential competitive impact precisely because the products of sets A and B are substitutes and in the same market.

Martin has argued that the judiciary has accepted the submarket approach to market definition in order to tighten the merger law. But this can be done, as the Brown case demonstrates, by lowering the size of the market share vulnerable under the law. There is, then, no need to narrow the market definition and artificially inflate the relative size of the merger. Nor is it a matter of indifference as to which way we turn the screw: the attempt to tighten the law by means of a submarket approach to market definition might have some unfortunate side effects.

A submarket approach in merger cases is not likely to increase the clarity, consistency, or acceptability of the law. What criteria are to be used in identifying a submarket? The six criteria enumerated by the Court in the Brown case are the same criteria which establish or identify the broad market. Some courts will accept at face value the market definition offered by the government, provided there is some supporting evidence; other courts, however, will demand that the relevant market must be drawn realistically, and the Brown decision will be cited as authority. Thus the definition of the market and the criteria used to identify it will vary from case to case, lending support to the argument that the antitrust laws are too capricious to be workable. And this argument will be bolstered by the allegation that the competitive impact of a merger is sometimes evaluated in a gerrymandered market. It is preferable, in this writer's opinion, to face the difficulties involved in identifying the true boundaries of the market than to use a submarket approach and run the risk of undermining the strong case for strict antimerger enforcement.

2. In finding the vertical aspect of the Brown-Kinney merger illegal, the Court considered three factors: the foreclosure effect, industry trends, and the competitive strength of the combination. Each of these three points will be briefly commented upon.

The Court did not attempt to analyze the competitive impact of the vertical merger at the manufacturing level; instead, it assumed as an article of faith that the permanent foreclosure of a market share which came to only 1.2 per cent of national sales would be inherently damaging to competition. Justice Harlan, in one of the separate opinions, expressed an opposite fear: that some of the independent retail stores would be prevented by the merger from dealing in Brown shoes. The possibility that the foreclosed manufacturers could sell to the foreclosed retailers was apparently not given any weight by the Court. The failure of the Court to go beyond the bare fact of market foreclosure testifies again to a point once made by Professor Mason: that the legal concept of monopoly emphasizes market exclusion [5]. It should come as no surprise, then, if small merger foreclosures are equated with monopolistic tendencies.

In judging the legality of the vertical merger at the manufacturing level, the

Court also considered the alleged industry trend toward concentration. It is clear that competition at some level may be threatened if only a few firms integrate into backward or forward markets, especially if these firms possess large shares at one of the industry levels. But it is not clear that a multifirm vertical integration movement will damage competition at any level: if 100 shoe manufacturers acquire all of the retail outlets, competition will not be restricted at either the manufacturing or the retailing level [6, p. 183]. Though the evidence in the *Brown* case did show that the number of manufacturers declined in the period 1947-54, it cannot be assumed that this was due, entirely or in large part, to the vertical merger movement in the industry; moreover, Justice Harlan admitted that the 4-firm, 8-firm, and 15-firm concentration ratios at the manufacturing level actually declined from 1947 to 1955.<sup>2</sup> Instead of arguing that the vertical merger movement in the industry threatens competition, the Court could just as easily have concluded that the vertical integration movement in the industry has worked to the disadvantage of the largest firms.

The Court also held that the vertical merger threatened competition at the retailing level. Justice Warren pointed out that a chain of vertically integrated outlets has lower costs than independent retailers because the wholesaler is eliminated and the chain units can purchase in large quantities. Justice Harlan argued that a vertically integrated chain can sell at a lower profit. Martin pointed out that these cost advantages were not given much weight by the Court. But the important point is that the Court failed to consider the attempt to lower costs as a legitimate purpose for merging; in fact the economic advantages of this particular merger were regarded by the Court as a threat to retail competition. With this stroke, the Court may have succeeded in closing the door on vertical mergers; for even if the market foreclosure is quite small, the merger can be condemned because of the adverse competitive effects at the forward market.

Martin concluded that the *Brown* decision does not make vertical mergers per se illegal but it "puts much less burden on the government than before" [3, p. 353]. If this view is correct (and this writer thinks it an understatement), it is important that we understand the costs of a tough law on vertical mergers. If there are genuine economies to be gained by vertical integration, business firms are under strong pressures to take advantage of them. This can be accomplished by the building of new assets or the acquisition of existing assets. In either case, the nonintegrated firms will eventually fall by the wayside. The pains of economic adjustment, however, may be more severe if these firms are gradually eliminated from the industry by the competitive pressures generated by new and more efficient capacity; for the sale of distressed assets to buyers inside or outside the industry is likely to be relatively disadvantageous

<sup>2</sup> According to the Bureau of Census studies of the 4-digit footwear industry, the 4-firm and 8-firm concentration ratios rose slightly from 1947 to 1954, while the 20-firm ratio remained constant. All three ratios were a shade lower in 1958 than in 1947. See [8, p. 27].

to the selling firms. A strict ban on vertical mergers may succeed only in increasing the social disutility of industrial reorganization without the compensating advantage of encouraging firms to achieve the most efficient structure.

If there is merit in the argument that mergers represent an efficient means of permitting firms to expand in order to achieve economies and a relatively painless way for inefficient firms to exit from the industry, then the new law on vertical mergers stands in need of modification. Provided the firm does not possess or is not acquiring a substantial market share, it should have the right to a defense that the merger will demonstrably lower costs. Such a modification of the law would retain for society the benefits of the merger device, without subverting society's efforts to prevent competitive damaging mergers; and it would take the sting out of the charge that the purpose of the Clayton Act is to protect producers from hard competition.

3. A close reading of the Court's approach to horizontal mergers in the Brown case suggests that the Supreme Court views a substantial increase in concentration, brought about by a merger involving a substantial share, as tantamount to a lessening of competition or tendency toward monopoly. Perhaps this is what Martin meant in arguing that under the Brown ruling horizontal mergers are to be governed by the incipency doctrine, whereas prior to 1950 they were governed by the more stringent Sherman Act test of illegality.

That an increase in industry concentration (rather than damage to competition) has become the gravamen of Section 7 is clear from a number of points in the Brown decision. The Court eschewed an analysis of market structure and conduct, viewed the instant merger against the backdrop of industry concentration trends, held (in another section of the decision) that the competitive vigor remaining after a merger is not relevant if oligopoly trends are present, argued that market shares as low as 5 per cent—at least in a fragmented industry—are substantial shares, and justified its over-all approach to merger legality on the ground that Congress had given a mandate to prevent tendencies toward concentration in their incipency. More significantly, the Court pointed out several times that there are three types of mergers which Congress wished to immunize from the law: mergers involving *de minimus* shares, failing companies, and small firms seeking to compete more effectively with the industry leaders. Presumably, all other mergers are illegal. Since it would be difficult to demonstrate on a priori grounds that all other mergers might damage competition, it is a fair inference that the focus of the law has been shifted from damage to competition to increases in concentration.

The above interpretation of the Brown decision forces me to question Martin's observations that market-share information will play a subsidiary role in future merger cases, that future courts may permit a merger involving a market share of, say, 5 per cent or more if industry competitors possess a larger share, and that the Brown decision confirms a rule of reason approach to merger legality. By emphasizing concentration, in the Brown case, the Court has pulled the rug from under the Pillsbury rule-of-reason doctrine and

replaced it with an approach that centers on market statistics, past and present.<sup>8</sup> If future courts scrupulously follow Brown, the frequency of the small-merger exemption may be small: even small mergers are now vulnerable under the law if industry trends are present, and it would take a most unimaginative antitrust prosecutor who could not find evidence of some kind of trend in the history of an industry.

In conclusion, the Brown decision crystallizes a question which long has plagued students of antitrust: how reliable are our predictive (analytical) judgments as to the probable competitive impact of a merger involving market shares of from, say, 2 to 20 per cent in industries having varying degrees of seller concentration, product differentiation, and entry barriers, as well as unpredictable firm behavioral patterns? My suspicion is that the variety of professional judgments concerning the impact of any given merger would be embarrassingly large. If I read Brown correctly, the Court has brushed aside the intricacies of the competitive impact question and has come down on the side of those who urge that antimerger policy should stress large numbers of seller alternatives and low seller concentration. And certainly this was what Congress had in mind in amending the Clayton Act in 1950. But even those who sympathize with this objective may be dismayed in the Brown ruling by the Court's confusing submarket approach to market definition and its overt hostility toward vertical merger. If the new look in antimerger policy is to have staying power, it must have a defensible economic underpinning.

<sup>8</sup> The above conclusion should be qualified. The Court held that the competitive strength of the Brown-Kinney combine might threaten the survival of nonintegrated firms. If this "soft competition" approach to mergers becomes precedent, then market statistics can be dispensed with altogether.

### The Brown Shoe Case and the New Antimerger Policy: Reply

I wish to reply to the first of the three points made by Professor Jones because his argument raises some fundamental questions about the scope and nature of economic theory and its usefulness in and relevance to the development of antitrust policy.

Jones argues that the Supreme Court's acceptance of the submarket approach in merger cases is undesirable, and he advocates the use of the same market concept in Clayton Act cases as in Sherman Act cases. But is it not quite consistent with acceptable economic analysis to use one market concept in evaluating the degree of competition or monopoly that has existed in the past and another market concept in forecasting the probable effect of a merger or acquisition on competition in the future? In the latter case one must not only draw inferences from incomplete information about what existed in the past but must also forecast future market boundaries. Even if unique, well-defined market boundaries existed in the past, we cannot know with certainty what they will be in the future. Fortunately, the Clayton Act standard is based on reasonable probabilities of future circumstances—market boundaries as well as market shares.

Aside from the distinctions between the nature of monopolization and Section 7 cases, however, I question Jones's basic assumption that "a market drawn to include competitive products and suppliers traces out the true boundaries of a market." In his first footnote Jones implicitly recognizes that substitutability is a matter of degree. He is willing to exclude from the broad market "extremely poor substitutes." But just what constitutes "extremely poor" is the question that gave rise to the submarket approach in the first place. The courts cannot relegate their criteria to an assumption in a footnote; they must reach findings of fact and conclusions of law relating to the question. Rather than forcing market realities into a dichotomy of substitutes on the one hand and extremely poor substitutes and nonsubstitutes on the other, the Supreme Court has adopted a concept that abstracts from reality to a lesser degree. In short, the Court quite properly rejected the notion that a unique boundary exists.

If the science of economics is to make a contribution to decision-making, whether private or public, economists must, it seems to me, avoid acting as if reality conforms to the simplifying assumptions of our models. I do not deny the usefulness of a theoretical model based on the assumption that there exists a "market comprising those firms selling substitute products to a common group of buyers." But that it exists in the shoe business or the electrical conductor wire and cable business is a fact that must be proven in court with legally acceptable evidence.

As Ross M. Robertson pointed out so clearly a decade ago,<sup>1</sup> the boundaries that Jones assumes to exist may not exist at all. Each good manufactured and offered for sale competes for buyers' dollars and, therefore, has substitutes.

<sup>1</sup> Ross M. Robertson, "On the Changing Apparatus of Competition," *Am. Econ. Rev.*, May 1954, 44, 51-62.

The substitutes have substitutes. The spatial aspect of competition alone gives rise to a problem of drawing a line around the firms that have a common group of customers. Unless Jones has made a value judgment on what constitutes "extremely poor" substitutability, his notion of the "broad market" is much broader than "flexible wrapping materials." It may even include the whole of economic activity in all the world. If it is less broad, it is because someone has made a value judgment and drawn a line. Whether drawn narrowly or broadly, can such a line be called "the true boundary"?

The recognition of the pervasiveness of substitutability and competition may lead to the conclusion that there is no monopoly problem. Obviously, no firm has the power to raise its prices beyond some upper limit without losing all its customers. But antitrust policy is concerned with protecting the public from *unlawful* restraints and monopolies. To catch violations in their incipency Congress has chosen to make unlawful all corporate acquisitions for which the reasonably probable effect is a substantial lessening of competition. In economic language we can state the criterion in these terms: Is it reasonably probable that the future effect of the acquisition will be to give the combined firm power to raise the price somewhat? That is, is there likely to be a limited range within which the price can be increased above the competitive level before the competition of substitutes reduces sales sufficiently that the firm finds it undesirable to raise prices further? A reduction of the number of firms selling a particular item may result in such power to raise prices somewhat. A merger between producers of substitutes may also reduce the danger of loss of sales to a particular substitute. If either possibility exists, the law is applicable. The relevant market in the former case is contained within the market relevant in the latter case.

Mr. Jones agrees with the desirability of tightening the merger law. He prefers that the government's burden be reduced by lowering the market share accepted as unlawful. Let us consider his example of six firms of equal size, three of which produce product A and three of which produce a substitute product B. Jones asks, if one of the firms acquires two others, what happens to its market share? His answer is that it has gone from one-sixth to one-half, irrespective of which two firms it acquires, and that this result is what the Court should examine in ascertaining the probable effect on competition in the market. I say that it makes a great deal of difference which firms have been acquired. If one accepts the market for products A and B together as one relevant market and also accepts the two submarkets as two additional relevant markets, then the effect of the merger on the market structure in all three markets depends on which firms were acquired. In Jones's first example—in which an A producer acquires the two other A producers—the acquiring firm's share of the A submarket goes from one-third to one, its share of the A plus B market goes from one-sixth to one-half, and its share of the B submarket remains at zero. In Jones's second case—in which an A firm acquires two B firms—the acquiring firm's share of the A submarket remains at one-third, its share of the broad market goes from one-sixth to one-half, and its share of the B submarket goes from zero to two-thirds. Is not all of this information relevant? Why throw it

away? Obviously, whether the probable impact will be to lessen competition substantially depends in part on how much the price of A can be varied before B is substituted for it, and vice versa. The probable impact also depends on how much the prices of A and B can be raised without some other substitute coming into consideration. Monopoly power in law as well as in economics is defined in terms of power to enhance price (not to infinity) and exclude entry. Owning potential entrants tends to give such power.

Perhaps the economic reasoning of the Court in *Brown Shoe* was really more sophisticated economically than Jones realized.

### On a Debt-Income Model of Consumer Instalment Credit Growth: Comment

The purpose of this note is to argue that the growth of the ratio of instalment debt outstanding to income is not adequately explained by Alain Enthoven in his article in the December 1957 issue of this *Review*.<sup>1</sup> His life-cycle model in Section I is not under discussion here, and its validity is unaffected by the following arguments. It is here contended that his debt-income model is technically misleading, if not positively erroneous. His assumptions are so strong that further analysis of their consequences reveals that, instead of growing to an asymptote, the debt-income ratio is constant (or becomes so as soon as the assumptions of the model have taken effect, which will happen within about three years at most).

Enthoven assumes that borrowings in each year are a constant proportion of income, that repayment conditions are constant, and that income increases by a fixed proportion each year. Under these conditions it may be seen that (a) total debt at the end of each year is the sum of those fixed proportions of borrowings in that and earlier years which are still outstanding (since repayment conditions are constant). Therefore (b) total debt is the sum of fixed proportions of income over the past few years (since borrowings are proportionate to incomes). Therefore (c) total debt bears a fixed ratio to income in the given year (since the income in each previous year is a fixed proportion of income in the given year). Hence Enthoven's conclusion that the debt-income ratio tends to a limit is correct only in a trivial sense; in fact it always equals the "limit." If the borrowing-income ratio is not equal to its constant value before year 0, say, perhaps because instalment credit was only then legalized, the debt-income ratio does not reach its constant value until year  $l$ , where  $l$  is the number of years for which contracts run. But it clearly must be constant from then onwards since the borrowing, if any, up to year 0 is irrelevant to total debt once it has all been

<sup>1</sup> Alain Enthoven, "The Growth of Instalment Credit and the Future of Prosperity," *Am. Econ. Rev.*, Dec. 1957, 47, 913-29.

repaid. The following paragraph summarizes Enthoven's mathematical formulation and explains how the confusion arises.

Enthoven writes

$$(1) \quad Y(t) = Y(0)(1+r)^t,$$

where  $Y$  denotes income,  $r$  its constant relative rate of growth, and  $t$  the number of years which have elapsed since the base year. Then if  $B(t)$  and  $R(t)$  are new borrowing and repayments in year  $t$ ,

$$(2) \quad B(t) = bY(t)$$

$$(3) \quad R(t) = L[B(t-1), \dots, B(t-n)],$$

where  $b$  is constant and  $L$  represents some linear combination. By definition,

$$(4) \quad D(t) - D(t-1) = B(t) - R(t).$$

Using (2) and (3) in (4)

$$(5) \quad D(t) - D(t-1) = bY(t) - L[bY(t), \dots, bY(t-n)].$$

For the sake of definiteness Enthoven now assumes that repayments are complete by the end of the third year, so (5) gives

$$\begin{aligned} D(t) - D(t-1) &= a_1Y(t) + a_2Y(t-1) + a_3Y(t-2) \\ &= aY(t) \end{aligned}$$

by using (1). Hence, summing,

$$\begin{aligned} D(t) &= \sum_{n=1}^t aY(n) + D(0) \\ &= \frac{a(1+r)}{r} Y(0)[(1+r)^t - 1] + D(0). \end{aligned}$$

Hence follows his basic conclusion:

$$(6) \quad \frac{D(t)}{Y(t)} = \frac{a(1+r)}{r} - \left[ \frac{a(1+r)}{r} - \frac{D(0)}{Y(0)} \right] (1+r)^{-t},$$

and so appears to tend to  $a(1+r)/r$  as  $t$  tends to infinity.

The basic cause of this confusion is that the repayment conditions are not specified, so that the constants in (6) are not so general as they appear. Suppose that of every dollar borrowed in year  $t$ ,  $p_0$  is outstanding at the end of the year,  $p_1$  at the end of year  $(t+1)$ , and by the definiteness assumption, none at the end of year  $(t+2)$ . Then

$$\begin{aligned} D(t) &= p_0B(t) + p_1B(t-1) \\ &= Y(t) \left[ p_0b + \frac{p_1b}{(1+r)} \right] \\ (7) \quad &= cY(t), \end{aligned}$$

giving a fixed debt-income ratio of  $c$ , as argued verbally above. Then

$$\begin{aligned} D(t) - D(t-1) &= cY(t) - cY(t-1) \\ &= aY(t) \end{aligned}$$

as above, where  $a = rc/(1+r)$ . This may be obtained directly, as follows:

$$\begin{aligned} D(t) - D(t-1) &= B(t) - R(t) \\ &= bY(t) - (1-p_0)bY(t) - (p_0-p_1)bY(t-1) \\ &\quad - p_1bY(t-2) \\ &= Y(t) \left[ p_0b + \frac{p_1b}{(1+r)} \right] \frac{r}{1+r} \\ &= \frac{cr}{1+r} Y(t). \end{aligned}$$

Equations (6) and (7) are consistent, since  $D(0)/Y(0) = c = a(1+r)/r$ , so that the square bracket in (6) is zero and  $D(t)/Y(t)$  is equal to  $c$ .

The observed growth in the debt-income ratio, which continued strongly until the late 1950's at least, can only be explained by a breakdown in one or more of Enthoven's assumptions; in particular, the constancy of the borrowing-income ratio expressed in (2) is not found empirically before the mid-1950's, and even now the ratio shows some signs of further growth.

### On a Debt-Income Model of Consumer Instalment Credit Growth: Reply

John and Ursula Hicks had a favorite saying for it: "Don't throw out the baby with the bath water." Mr. Oliver has found a little bath water, but he is wrong in suggesting that he has thrown out my baby. His point is correct, as far as it goes, but it is a minor technical point that does not affect the validity of my interpretation of the postwar growth of consumer instalment credit [3]. Although his note is useful, he has not established that my "debt-income model is technically misleading, if not positively erroneous."

As Mr. Oliver indicates, I did assume that income in the year  $t$ ,  $Y(t)$ , grows at a constant annual percentage rate,  $r$ , i.e.,

$$(1) \quad Y(t) = Y(0)(1+r)^t;$$

that new borrowing in the year  $t$ ,  $B(t)$ , is proportional to income in the same year, i.e.,

$$(2) \quad B(t) = bY(t);$$

and that repayments in the year  $t$ ,  $R(t)$ , are a linear combination of borrowings in the previous  $n$  years, i.e.,

$$(3) \quad R(t) = L[B(t-1), \dots, B(t-n)].$$

And, as Mr. Oliver indicates, these assumptions do imply that the debt-income ratio must become constant by the  $n$ th year. But assumptions (2) and (3) were made gratuitously, to provide a logical basis for the equation

$$(4) \quad D(t) - D(t-1) = aY(t),$$

which states that "the absolute increase in the stock of debt outstanding each year is proportional to a variable which grows at the same rate as income" [3, p. 923]. As shown in my article, equations (1), (2), and (3) together imply (4). But the reverse is not true. That is, (4) can be valid even under conditions in which (2) and (3) are not satisfied. Moreover, my model rested entirely on equations (1) and (4). Equations (2) and (3) did not reappear once they had served the purpose of providing a basis for (4). Therefore, since (2) and (3) are unnecessary, and have the overly strong and unwanted implications pointed out by Mr. Oliver, I shall apply Occam's Razor and abandon them. The basic assumptions of the model then are equations (1) and (4), and the whole analysis that follows them stands unharmed. This model, incidentally, is essentially the same as models used by Gurley and Shaw [4] and Domar [2] in discussions of the growth of other kinds of debt.<sup>1</sup>

How good is the assumption expressed by equation (4)? As I showed in 1957, equations (1) and (4) imply:

$$(5) \quad D(t) = \frac{a(1+r)}{r} Y(0)[(1+r)^t - 1] + D(0)$$

$$(6) \quad \frac{D(t)}{Y(t)} = \frac{a(1+r)}{r} - \left[ \frac{a(1+r)}{r} - \frac{D(0)}{Y(0)} \right] (1+r)^{-t}$$

$$(7) \quad \lim_{t \rightarrow \infty} \frac{D(t)}{Y(t)} = \frac{a(1+r)}{r}.$$

Fitting (1) to personal income for the years 1945 and 1963, one obtains an annual average growth rate of about 5.7 per cent. Fitting (5) to personal income and consumer instalment credit outstanding for the same years, one obtains a value of  $a$  of .0094.<sup>2</sup>

<sup>1</sup> If I were now able to rewrite the article in the light of Oliver's criticism, I would merely delete the lines between the equations numbered (3) and (6) on page 923—corresponding to equations (1) and (4) here—together with the attached footnote, and replace them by the words "Second, we assume"; and also delete the references to the assumptions expressed here by equations (2) and (3) earlier in the paper, while leaving everything that follows unchanged.

<sup>2</sup> The data for these and all other calculations in this discussion are taken from [6]. The income data are personal income from Table C-14, p. 224. The instalment credit data are from Table C-49, p. 267. The borrowings and repayments are from Table C-50, p. 268. The 1963 data are Council of Economic Advisers' estimates. All other income data are from the Department of Commerce. All other data on instalment credit are from the Board of Governors of the Federal Reserve System.

One finds a good deal of cyclical fluctuation if one calculates the actual ratio of  $D(t) - D(t-1)$  to  $Y(t)$ , i.e.,  $a$ , for each year in the postwar period. Although the three-year averages shown in Table I suggest that  $a$  has declined some in the past six years, the 1962 and 1963 values were above the average for the period as a whole. Considering the fact that the  $D(t) - D(t-1)$  series is the difference between two relatively large variables, one of which is subject to quite large cyclical variations, the parameter  $a$  appears to have been reasonably stable.

As I showed in the 1957 article and intend to show again later in this note, the model based on equations (1) and (4) does provide a good description of what actually has been taking place; that is, an asymptotic convergence of the debt-income ratio. However, the implications correctly

TABLE I—AVERAGE VALUES OF THE RATIOS OF CHANGE IN DEBT  
TO INCOME AND BORROWING TO INCOME\*

Years	$a = \frac{D(t) - D(t-1)}{Y(t)}$	$b = \frac{B(t)}{Y(t)}$
1945-63	.0091	—
1946-48	.0112	.063
1949-51	.0096	.091
1952-54	.0098	.108
1955-57	.0106	.122
1958-60	.0077	.121
1961-1963	.0081	.125
1962	.0102	.125
1963	.0122	.131

\* These are simple unweighted arithmetic averages.

drawn by Mr. Oliver from equations (1), (2), and (3) are quite clearly inconsistent with the data; since 1945, the debt-income ratio has increased steadily and has not become constant. Therefore, either or both the hypotheses represented by (2) and (3) must be abandoned. Mr. Oliver has made a useful contribution in pointing this out. But what is to replace them? This would be an interesting research project for someone with more time than I have. I must limit myself to a brief consideration of a few possibilities.

First, what is the evidence on equation (2)? As Mr. Oliver points out, the borrowing-income ratio is growing. In fact, using personal income and instalment credit extended, the ratio has more than doubled over the period under investigation, although it has changed little since 1955. This is shown in Table I. It reflects the removal of restrictions on this kind of borrowing in 1946 and 1947, the increasing number of people using instalment credit, and the penetration of instalment credit into new areas. It may also reflect what is, in effect, refinancing of existing debt by further use of instalment credit.

Second, what is the evidence on equation (3)? My present circumstances do not permit the detailed sort of econometric investigation one would like to do. For example, one should attempt to fit a different function to each of the major types of instalment credit (automobile paper, other consumer goods paper, repair and modernization loans, and personal loans). However, one rough check shows that total repayments on all instalment credit each year from 1948 to 1963 have stayed very close to the average of borrowing in that year and the two preceding years. The variations about this average do not show any discernable trend.<sup>3</sup> This suggests that there hasn't been any strong change in the pattern of repayments, but confirmation of this conjecture would require more detailed analysis.

I have, for several years, wanted to go back and examine the post-1956 data to see whether the pattern of growth of consumer instalment debt has been consistent with my model. I am grateful to Mr. Oliver for providing the occasion for doing this. In making such an examination, it is important to bear in mind that the purpose of the model was not to predict income or the debt-income ratio. It is not entirely clear that one can expect reliably accurate prediction from any econometric model; surely not from a simple two-parameter model in a complex multivariate situation. The purpose of the model was to show the logical compatibility of a growth rate of instalment debt substantially in excess of the growth rate of income with the continued steady growth of income. Moreover, after allowing for cyclical fluctuations, the growth of the debt-income ratio between 1945 and 1956 did display the pattern of asymptotic convergence predicted by the model.

Between 1956 and 1963, the average annual growth rate of income has been lower than in the preceding eleven years. Fitting  $(1+r)^t$  to the end points, one obtains about 6.2 per cent for 1945-56 and about 4.8 per cent for 1956-63. If one had had to make predictions in 1956 of the debt-income ratio in the early 1960's, one possible procedure would have been to use the value of  $a$  derived from the 1945-56 period and to make conditional predictions based on alternative assumptions about the rate of growth of income. The trouble with this is that  $a$  is not necessarily independent of  $r$ . In fact, in my original derivation of  $a$ , the one attacked by Mr. Oliver,  $a$  and  $r$  were positively related, so that a decline in  $r$ , *ceteris paribus*, would entail a decline in  $a$ . Mr. Oliver has forced me, at least temporarily, to be agnostic about the relationship of  $a$  and  $r$ . But I neither need to assume nor would I feel justified in assuming that they are unrelated, especially in view of the fact that  $a$  also fell after 1956.

An alternative procedure would be simply to extrapolate from 1956 onward using the model with parameters derived from the 1945-56 data, and to compare the extrapolated debt-income ratios with the actual ratios. This comparison is shown in Table II. The fit is not too bad when one considers the simplicity of the model. For example, by 1963 the extrapolated

<sup>3</sup> The average ratio of  $R(t)$  to  $.33[B(t) + B(t-1) + B(t-2)]$  in the years 1948 to 1963 is 1.008. With the exception of two years in which the ratio reaches 1.083 and 1.089, the greatest deviation from the average is less than .03.

debt-income ratio is about 12.5 per cent while the actual ratio reached 11.6 per cent.<sup>4</sup>

Thus, in fact, predictions of the debt-income ratio generated in this way turned out to be high despite the fall in  $r$  which, if  $\alpha$  were constant, would have the effect of increasing the debt-income ratio. The reason for this can be found in the decline of  $\alpha$  after 1956. Nevertheless, Table II shows quite clearly that, allowing for cyclical fluctuations, the debt-income ratio did follow the pattern of asymptotic convergence suggested by the debt-income growth model.

TABLE II—ACTUAL AND EXTRAPOLATED GROWTH OF INCOME  
AND INSTALMENT CREDIT, 1956-1963\*

	Actual	Extrapolated	Actual	Extrapolated	Actual	Extrapolated

1959	383.9	399.1	39,245	43,680	.1022	.1094
1960	401.3	423.9	42,832	48,178	.1067	.1137
1961	417.4	450.3	43,527	52,957	.1043	.1176
1962	442.1	478.4	48,034	58,032	.1086	.1213
1963	463.0	508.2	53,675	63,424	.1159	.1248

\* Extrapolation based on debt-income model fitted to 1945 and 1956 data.

In discussing an analysis by Gilbert Burck and Sanford Parker [1], I included the following footnote in the 1957 article [3, p. 927, n. 21]:

Burck and Parker . . . used an incorrect method of extrapolation of the rate of increase of the debt-income ratio: ". . . instalment debt outstanding has grown from 5 per cent of consumers' disposable money

<sup>4</sup> The values for income, debt, and therefore  $\alpha$  and  $r$  used here are slightly different from those shown on page 926, Table III, of my 1957 article. The reason for this is that, in the interim, for reasons best known to the Department of Commerce and Oskar Morgenstern [5], the data for the years 1945-56 have been revised. However, the change is too small to have any noticeable effect on this analysis. I have used the new data to achieve consistency with the subsequent years.

income in 1948 to 10.9 per cent in 1955. If this rate of increase were to continue for another seven years, instalment debt outstanding would have to rise to about 17 per cent of disposable income in 1962." Apparently they extrapolated linearly the change over the previous seven years. If this is what they understand by "the rate of increase of instalment debt," it is not surprising that they predict that it must slow down, for this "rate," if extrapolated, would lead eventually to an infinite ratio of debt to income no matter how small a positive increase took place in the ratio during the base period. In terms of personal income and instalment debt, their figures would be a ratio of debt to income of .0431 in 1948 and a ratio of .0948 in 1955 (see Table II, above), or an increase of .0517. Extrapolating linearly for another 7 years by adding the change over the past 7 to the 1955 ratio, one obtains .1465 as their "prediction" for 1962. The authors make it clear that they do not believe that the economy could support such an in-

TABLE III—LIMITING DEBT-INCOME RATIOS IMPLIED BY  
THE DATA OF SELECTED SETS OF YEARS

Personal Income and Instalment Debt	$a$	$r$	$\lim \frac{D}{Y}$
1945-56 (1957 Data)	.0107	.0602	.188
1945-56 (1964 Data)	.0106	.0623	.181
1956-63 (1964 Data)	.0078	.0482	.169
1945-63 (1964 Data)	.0094	.0568	.176

crease. On the basis of equation (9), the extrapolated debt-income ratio for 1962 is .1239.

In fact, as indicated in Table II, the 1962 ratio turned out to be 10.9 per cent. Thus, my extrapolation was clearly much closer to the mark than the one implied by Burck and Parker's model.

Alternatively we can fit the model to the end points of the 1945-63 period, and compare it with the previous results. This is done in Table III.

These calculations suggest that the 1956-63 experience has been consistent with the conclusions reached on the basis of the 1945-56 data. In particular, the limiting debt-income ratio has remained around 18 per cent. Looking ahead, the rate of convergence can be expected to decline. If personal income continues to grow between now and 1970 at the 1945-63 average rate, and if the forces that have generated the growth of debt in those years continue to operate unaltered (assumptions, not predictions), by the end of 1970, the ratio of consumer instalment debt to personal income should reach about 13.5 per cent.

**Economic Forecasting When the Subject of the Forecast  
Is Influenced by the Forecast: Correction**

In the September 1963 issue of the *Review*, the first instead of the second version of a communication by Emile Grunberg and Franco Modigliani was mistakenly published, "Economic Forecasting When the Subject of the Forecast Is Influenced by the Forecast: Comment." In his "Reply," Murray C. Kemp replied to the unpublished second version. Fortunately, only a few of his remarks and references require clarification.

In particular, Kemp's two sentences on page 739, lines 8-13, refer to the following statement by Grunberg and Modigliani (which should be substituted for their statement on page 737, lines 9-13):

In short we suggest that, before we can reach sensible conclusions on this complex issue, we need to learn to construct models whose behavior equations are more directly tied to optimizing behavior of the individual units, and which take seriously into account rationality in the formation of expectations.

Further, the paragraph of Kemp's, beginning on page 739, line 25, referred to the following footnote by Grunberg and Modigliani (which should be inserted after the word "possible" in line 14, page 734):

Kemp's use of the terms "accurate" and "perfectly accurate" seems not very felicitous. Our reasons for preferring in our paper the term "correct" is that "accuracy" (and *a fortiori* "perfect accuracy") does not have a very precise meaning. Indeed, "accuracy" is better viewed as a relation than as a property. Surely, perfect accuracy does not exist even in astrophysics. We defined "correct" as what might be termed "acceptably accurate": a prediction where at any time  $t$  the observed value  $x_t$  falls within an interval between  $x^* + n$  and  $x^* - n$ , where  $n$  is an arbitrary variable depending on the purpose of the prediction and thus ultimately subjective.

In addition, the second version contained the following footnote, not referred to by Kemp, which should be inserted after the word "discontinuities," page 736, line 20:

Needless to say, the shape of the dashed portion of the  $R$  function in our graph is purely illustrative. It is conceivable that the  $R$  function might actually reach the upper boundary for some value of  $y^*$  less than the upper bound of  $y$ , and before intersecting the requirement function. But thereafter, since it cannot pierce the upper boundary, it must either run along it or fall again below it. In either case, as long as it is continuous, it must intersect or touch the requirement function at least once, if not earlier then at least when  $y^*$  equals the upper bound of  $y$ . Similar considerations apply, *mutatis mutandis*, to the lower bound.

## BOOK REVIEWS

### General Economics; Methodology

*Die Grundannahmen der Preistheorie. Eine Kritik an den Ausgangssätzen der mikro-ökonomischen Modellbildung.* By GERHARD KADE. Berlin and Frankfurt am Main: Verlag Franz Vahlen, 1962. Pp. 176. DM 18.

This book by Dr. Gerhard Kade is a small volume of 176 tightly printed pages. It is a *Habilitationsschrift* which was published on recommendation of the Faculty of Economics and Social Sciences at the Free University in West Berlin.

The subject matter is neoclassical economic theory, defined as all those economic theories which adopt the market model of perfect competition. This comprises a good part of contemporary economic theory. To get into sharper focus the problems with which the author is concerned, a few preliminary observations may be made on the nature of theories in social sciences in general and economics in particular.

Economics as a social science is an empirical science (*Erfahrungswissenschaft*). Economic events—similar to events in other social or natural sciences—are part of the real world. In an effort to understand these events, theories were developed, at first intuitive ones, later axiomatic ones. It is generally agreed that, once it becomes possible to axiomatize the contents of a field of knowledge—which depends, of course, on how well such a field is studied and understood—it may lend itself to mathematical treatment. If the latter is the case, the possibility exists that, in a deductive way, new and so far undetected relationships may be discovered. This may then lead to considerable new insights as was the case for example in modern physics. However, in any empirical field, the preconditions for a later fruitful mathematical deductive analysis—no matter how refined and powerful it may be—are good axioms or good basic assumptions to start with. These axioms are statements about events in the real world and the better they describe these, the better they are. Here Kade's problem begins.

He scrutinizes carefully what are the underlying axioms of neoclassical price theory, or better, neoclassical decision making. He singles out three fundamental ones which suffice to explain the working of the system as conventionally stated. These are (a) the information axiom, (b) the axiom of rationality, and (c) the axiom of reaction. These axioms, which are basic for the economic content of the neoclassical theory, are found seriously deficient. They do not properly account for what is observed in reality. The reason for this inadequacy is partly owing to the fact that, when these axioms were formulated—at and before the time that economics was mathematized—the relationship between alternative economic choices and resulting decisions was poorly understood. In addition, these axioms include traceable notions of earlier times as to what should be the order of economic things (here the author lists, e.g., apologetic efforts of interested groups), the role of the state in economic

affairs, and an optimum which the system is supposed to grind out. In any case, whatever the deficiencies of the axioms were, they have come down to us and pervade present neoclassical price theory.

What does the author consider the most important deficiencies? We may quickly list them. First, there is the assumption of full information or transparency of all markets. Second, there is the assumption that decision-making units try to maximize economic gains and that doing this will not only lead to an "optimal" solution for each individual but also for society as a whole. Chances are that a "maximum" in a mathematical sense is not a true "economic optimum." Whether it is actually an economic "optimum" depends on the assumed underlying economic behavior. Different assumptions as to economic behavior will lead to different optima. Third, there is the assumption of the existence of smooth and differentiable functions which are difficult to reconcile with known indivisibility of many goods and factors of production. In short, the desire to use an elegant mathematical apparatus (something the author refers to as "*Analogiefreudigkeit*," which means a joy derived from the fact that the same methods of analysis can be applied as in the natural sciences) led often to the uncritical acceptance of simple, but, *helas*, to a large extent irrelevant axioms. Consequently, neoclassical theory, though logically consistent the author argues, is largely empty in an economic sense. An implication is that economic policy decisions based on such a theory must be viewed with utmost suspicion. This seems to be the essence of the book.

It is not necessary to delve further into Kade's objections to neoclassical theory. They are well known, though—this must be admitted—often conveniently ignored. It is unfortunately very often the case nowadays that the elegance of a mathematical model and its logical consistency often seem to be more important than its economic content. Yet one should not be too pessimistic. In time new axioms will be, no doubt, forthcoming and they will better describe what is going on in the real world than those we inherited from the eighteenth and nineteenth centuries. The appearance of game theory may be cited as an example of a possible fruitful breakthrough leading to the creation of new axioms of economic behavior.

The merit of Kade's book is the emphasis which he puts on the sharp distinction between the economic content of an economic model which depends on underlying basic assumptions and its tautological mathematical structure. Concern about these problems is certainly very important, yet in the opinion of this reviewer there is no need for a new *Methodenstreit* about what should rank higher in economics, efforts to improve axioms or developing mathematical deductive methods. Both are essential. If there is at present an imbalance, as the author asserts, one may guess that it is owing to the fact that mathematization of economics may have occurred at too early a stage historically. Contrary to some natural sciences, too little was evidently known about human economic behavior to permit meaningful axiomatization. Whether the use of mathematics in economics has been derogative to efforts to obtain better axioms, and thus has handicapped the development of economic theory, is a very difficult question. This reviewer would be very reluctant to accept the author's final conclusion that this was inevitable and actually so.

Kade wrote a stimulating, if not easy to read, book and, though in the treatment of his subject the diagnosis is much longer than the cure, it should be rewarding to those who are interested in basic problems of economic theory.

Related Empirical Studies; History of Economic Thought**

*Approaches to Dynamic Investment Planning.* By STEPHEN A. MARGLIN.  
Amsterdam: North-Holland Publishing Company, 1963. Pp. x, 162.  
\$5.00.

This concisely written monograph is concerned with the following problem in the planning of public investment: Suppose that benefits from undertaking a project increase with calendar time. If the cost of construction remains constant (or increases less rapidly than benefits), the social value of the project may vary with the time at which construction begins. The problem for investment planning is to determine the optimal time for undertaking construction of the project.

Marglin begins with the analysis of a simple but elegant formal model. Construction costs occur at a single point in time while benefits occur as a perpetual stream beginning at the time of construction. The value of the rate of benefits is the product of a component depending only on calendar time and a component depending only on time elapsed since construction. The first component may be identified with price (for "small" projects) and the second with quantity of benefits.

The criterion for social value of a project is the present value of net benefits. The discount rate is taken as given. It represents "... the community's *marginal* rate of substitution between present and future consumption ..." (p. 143). In the absence of budget constraints, this criterion is clearly an appropriate one. At the most fundamental level investment decisions represent the selection of alternative paths for consumption; in the case of public investment, selection among projects represents choice among alternative paths for consumption faced by the community.

Marglin contrasts selection of time for construction by maximization of present value with construction of a project whenever its present value becomes non-negative. The latter rule, called by Marglin the "Sophisticated Static Rule," may lead to premature construction of projects. The principal conclusion of this part of the analysis is that "durable investments must be planned within a framework that includes the dynamic question of the choice of construction time as an integral part of the investment decision" (p. 31).

From the initial framework just described, Marglin goes on to consider investment planning subject to budget constraints. In the most detailed model discussed by Marglin there are  $m$  projects and  $T$  construction periods. The present value of benefits for each project is taken to be a function of construction outlays on that project in each of the  $T$  construction periods. The total construction outlays on all projects in a given period must be less than or equal

to the construction budget provided for that period. The budget for each period is taken as fixed in the sense that construction expenditures in a given period may not exceed the budgeted level. No carry-over of funds from one construction period to another is permitted. However, unspent funds are credited to the investment plan at a price which is taken to reflect the social value of these funds in the private sector.

The critical assumption in Marglin's formulation of the problem of investment planning subject to budget constraints is the following: "we simply assume the existence of a set of techniques for finding the optimal dynamic plan for an individual project in isolation, and address ourselves only to the extra problems posed by budget constraints" (p. 73). The techniques to which Marglin refers involve the calculation of the present value of benefits for each project. As in the problem of investment planning without budget constraints, the discount rate is taken as given.

The criterion for the social value of an investment plan is "to find the allocation of the budgets which maximize the sum of project net present values and the net present value of slack [unspent funds] subject to the condition that the sum of project outlays in each period not exceed the period's budget . . ." (p. 101). In computing the value of Marglin's criterion for any particular investment plan, the procedure is to calculate the present value of net benefits for each project; both benefits and construction outlays are discounted at the given social rate of discount. The present values for each of the projects are then added together to obtain a total present value for the investment plan. An optimal plan is one which maximizes total present value for all projects together with the present value of unspent funds subject to the budget constraints.

The crucial assumption implicit in Marglin's procedure is that an appropriate rate of discount for the evaluation of individual projects (or, for that matter, for devising an optimal dynamic plan for an individual project) can be taken as given independently of the construction budgets available in each of the construction periods. There is one set of circumstances in which this assumption is consistent with selection of an optimal path for community consumption. This is that *none* of the budget constraints is "effective," that is, that funds provided by the construction budget for each period are greater than or exactly equal to the construction outlays for that period which would be optimal *in the absence of* budget constraints.

The problem of investment planning without budget constraints is not completely uninteresting. However, for the application which figures most prominently in Marglin's discussion—water-resources planning—the most interesting problems appear to involve budget constraints which are effective. In this case no "set of techniques for finding the optimal dynamic plan for an individual project in isolation" exists.

There is a further problem in the application of a present value criterion like that employed by Marglin even where budget constraints are absent. Except for the trivial and uninteresting situation in which the community's marginal rate of substitution between consumption in any two periods is independent of the levels of consumption in either of the periods (and all

other periods), the assumption of a given rate of discount requires in essence that the optimal solution of the investment problem be known in advance of computation of this solution by maximization of present value.<sup>1</sup> Stated this baldly, the assumption of a given rate of discount is palpably absurd. A procedure like that advocated by Marglin cannot provide an appropriate basis for investment planning in either public or private sectors.

A major portion of Marglin's book is devoted to the consideration of investment plans which are optimal by his criterion. In general, the "optimal" plan corresponds to the solution of a nonlinear-programming problem. Marglin presents what amounts to a survey of methods for computing solutions to concave programming problems as discussed by such authors as Arrow and Hurwicz. In view of the requirement that the optimal solution be known in advance, implicit in the definition of the criterion for optimality, these computational details are of little economic interest.

From the point of view of water-resources planning, Marglin's chief contribution in this monograph is his elegant and lucid analysis of the choice of a time for construction in the absence of budget constraints. Despite the defects of Marglin's approach to investment planning subject to budget constraints and the inadequacy of his proposals for computation of investment plans, the monograph may provide useful insights into the institutional framework within which an economically sound approach to these problems must be formulated.

DALE JORGENSEN

*University of California, Berkeley*

<sup>1</sup> This point has been made very forcefully by J. Hirshleifer in his already-classic article, "On the Theory of Optimal Investment Decision," *Jour. of Pol. Econ.*, Aug. 1958, p. 340.

*The Growth Multiplier and a General Theory of Economic Growth.* By VIKAS MISHRA. New York: Asia Publishing House, Taplinger Distributor, 1962. Pp. 164. \$5.00.

If one has recently acquired some fresh ideas about a theory, quite as a matter of course one wants to bring it to the attention of others. A reliable means to this end is to use the expression "A General Theory of . . ." in the title. But this has its liabilities, for even Keynes' *General Theory* turned out to be not quite as "general" as he thought.

The title of the present book is somewhat misleading and pretentious. The book may be regarded basically as a descriptive analysis of what I might call a dynamic input-output model, though the author neither uses the term "input-output" nor gives any mathematical formulation.

The book consists of two parts: Part I deals with the analytical apparatus; Part II takes up economic evolution in the expansive time-horizon. In Part I the author discusses the basic concepts and definitions and presents an analytical apparatus which he uses to discuss the way the process of

economic growth could start and develop within the framework of this system. An attempt is made to incorporate in a single formulation the explanations of fluctuations in economic activity, the transition of an underdeveloped subsistence economy to a growing economy and sustained growth equilibrium. In Part II he shows to what extent the analytical apparatus can be applied to explain both the present and future evolution of an economic society. The central concept the author uses in his formulation of growth theory is the growth multiplier.

The growth multiplier is defined as "a moving summation process of the various investment multipliers in an economy where an investment multiplier is conceived of as an investment *potential* function of a specific investment *current*" (p. 100). By investment current, Vikas Mishra means autonomous investment and by investment potential, induced investment. Thus the investment multiplier is the ratio of induced investment to autonomous investment. But it is *not* the Kahn-Keynes type of the investment multiplier ( $dY/dI$ ). In his formulation the total investment potential can be divided into the direct investment effect arising from the Hirschman type of linkage effect and also into the indirect investment effect arising from the familiar multiplier and accelerator interaction. A set of such investment multipliers—under various conditions, with varying volumes, spreads, and intensities—will establish an investment multiplier complex which, in the process of interaction with the economic activity complex, brings about the growth multiplier. The initial investment current may start from any sector, but how crucial a sector is must be evaluated in terms of the proportionate magnitude of its contribution to the total national product and also of the relatively large prospects of technological change (or innovation) in that sector. In terms of the transition to the phase of self-sustained growth, the entry of the crucial sector into the orbit of interaction process is a precondition for the take-off stage in economic growth.

The process of economic growth is viewed as comprising two distinct phases, that is in his terms "Release" (Take-Off) and "Equilibrium" (Sustained Growth). The Release phase is a sharp rise in the rate of investment current and also investment potential, whereas the Equilibrium phase treats them as relatively stable. For him, Cyclical disequilibrium and Trend disequilibrium can be explained via the direct and indirect investment effects.

To this reviewer it is not entirely clear what is meant by the growth multiplier. Since Mishra defines the growth multiplier as a moving summation, it seems to me that it may be considered as a summation of "dynamic multipliers" of all sectors. At any rate the present book is too general to draw any specific conclusions about the way an economy can develop and achieve balanced growth. My admiration of this work would have been greater if the author had presented his model of economic growth as a system of equations, at least in the footnotes or in the appendix.

RYUZO SATO

*University of Hawaii*

*Keynesianism—Retrospect and Prospect: A Critical Restatement of Basic Economic Principles.* By W. H. HUTT. Chicago: Henry Regnary Company. Pp. xi, 447. \$7.50.

In this book Professor Hutt endeavors comprehensively to examine and "refute" the Keynesian system. After briefly stating the Keynesian thesis and its consequences, as he understands them, he begins with several valuable chapters on the nature of money and the functioning of the pricing system. In Chapter 8, however, a highly individual definition of income is introduced, and for the remainder of the book Hutt's criticism, much of which is valid and valuable, is needlessly obscured by an almost Keynesian determination to make the reader learn a new language, which is about 50 per cent tautology. In this review I shall concentrate upon the substance of Hutt's argument, as I understand it.

What is Hutt really shooting at? He takes as his basic target (p. 33) a quotation from Harrod: "If a certain level of interest is established which is inconsistent with full activity, no flexibility or mobility in other parts of the system will get the system to move to full activity." In other words, Keynesian unemployment equilibrium does *not* depend on sticky prices and wages. This proposition of Harrod's (in its nondefinitional sense) Hutt has no difficulty in demolishing in his Chapter 9. He *seems* to use the standard refutations of the "wealth" effect, and repercussions upon the marginal efficiency of capital, pointed out by Haberler, and in my *Keynesian System*, and, as far as that goes, by Keynes himself in Chapter 19 of the *General Theory*, but the most original part of his emphasis is to point out that *relative* price changes, by indicating and releasing new wants and new investment outlets, will favorably affect the MEC schedule. As in my *Keynesian System*, though not as carefully or explicitly, he uses spontaneous shifts in wants and methods to question the idea of any necessary capital glut or state of "full investment." He shares my belief that any actual state of capital "glut" is the product of an unfriendly institutional environment, not physical law.

It would appear from all this that Hutt is a hard-shell, sound-money, and price-flexibility man who would never increase  $M$  or certainly not  $MV$ . But somehow this is not altogether the case. In an aside (pp. 125-26) reminiscent of some of Keynes' qualifications, he seems to admit that an expansion of  $MV$  to "remedy a *purposeless* deflation" is all right, and that deflations have sometimes been "misconceived or ill advised." So we do have to exercise some practical judgment after all! This should have induced more charity toward the "right wing" Keynesians among whom he numbers the reviewer but they come in for special virulence. In this connection I should explain that by the "undogmatic disciples of Keynes" (p. 435), whom he says I neglect to mention, I meant Gottfried Haberler and John Jewkes. I can see no reason why he should quote Haberler with approval throughout, while discharging considerable indirect artillery in my direction, when Haberler's position and mine, as he must know, are practically identical. If this be "Keynesianism," I must plead guilty, of course. But let me pass on to such differences of substance as I think still exist between Hutt's views and mine.

Both Hutt and I, as I see it, believe that economic progress is essentially open-ended. But we both also believe that, through the inevitable discontinuities of a continual advance into novelty, fluctuations sometimes occur. Hutt, *most* of the time, talks as if he thought price and interest-rate flexibility *alone* could always contain these fluctuations within a socially tolerable degree of fluctuation. Now with this position I disagree, and I refuse to rule out entirely the use, in appropriate circumstances, of deficit finance. Hutt merely *asserts* that such a policy must always lead to inflation. He does not prove it. Just because easy money is not the cure-all that the streamlined Keynesians now teach it to be, does not mean that it is always bad. Indeed we have seen that even Hutt weakens a bit in his all-out dogmatism. Unemployment, like fever, is a product of many different forces, and because a medicine does not work in one case does not prove it is always useless.

But deficit finance and easy money are certainly, today, products that have been oversold. I am distressed that Hutt should have couched his, frequently, most valuable deflation of their claims in language so vague and so intemperate as to lose him much of his audience. He frequently misstates Keynes, and only restrictions of space keep me from stating some of his errors. But Hutt may have something on his side. When someone writes a careful, temperate criticism of Keynes, like my *Keynesian System*, it often gets shrugged off—unread—as “saying nothing new.” Maybe the criticism has to be shrill to be heard! If so, this is a deep reflection upon current U.S. scholarship.

DAVID MCCORD WRIGHT

*University of Georgia*

*Price Theory and Its Uses.* By DONALD S. WATSON. Boston: Houghton Mifflin Co., 1963. Pp. xiii, 431. \$6.50.

In *Price Theory and Its Uses*, Donald S. Watson organizes his material in a customary way. The theory of demand comes first, with chapters on the demand concept, price elasticity, neoclassical utility, modern utility, indifference curves, and selected extensions (income elasticity, cross-elasticity, durables, expectations, market structures). The theory of the firm follows, with chapters about profit maximization, production functions, optimal combinations, cost functions, and linear programming. Competitive pricing comes next, with chapters about supply curves, short-run equilibrium, long-run equilibrium, general equilibrium, policy implications, and disequilibrium. Monopoly pricing follows, with chapters headed monopoly price and price discrimination. Next is imperfect competition, divided into monopolistic competition, oligopoly models, oligopoly pricing, and nonprice competition. Watson concludes with incomes as prices, devoting one chapter to factor pricing and one to wages.

How do you judge a theory text? Substantively, I hope you want it to accomplish the following, among other things.

It presents the intersection of demand and supply, not as a deterministic outcome, but as an estimator of the expectations of quantity, average price,

successful traders, and gains from trade—and as an estimator that, in the two tests so far made, has proved biased and subject to large error even with atomism. It recognizes that these expectations may be affected by search and transaction costs and by the transaction system (auction, etc.). It sees that a testable theory of value would predict which system arises where and produce a probability function for quantity, etc., with each. It shows that parallel indifference curves would mean not only that the income effect is zero, but that alternative dollar measures of a participant's gain from trade converge, and that these dollars can be summed over all participants to provide a measure of exchange efficiency.

It reveals, even to undergraduates, that equilibria may not be unique, that determinancy is not settled by counting unknowns and equations, and that stability in a market depends on much more than the slopes of its demand and supply. In any event, it always distinguishes between equilibrium and actual values, and, recognizing that disequilibria are pervasive, it explains that what really needs to be predicted are the time paths of variables.

It discloses that the explanatory variables in predictive demand and supply functions include previous prices (and therefore commitments and expectations); that responses to prices, advertising, etc., are subject to distributed lags; that individual demands cannot simply be summed unless they are independent; and that a curve portraying simultaneous alternatives does not indicate reversible paths over time or its elasticity relate to price changes. It does not confuse elasticities and slopes or label all of a nonhomogeneous curve elastic.

It specifies that demand is long-run, not if it shows pounds bought during a decade instead of a week, but if it shows pounds per week (or decade) that would sell at each price after it (and incomes, etc.) were constant for a decade. By a short-run function it means not what happens soon but what would happen if no start were made on certain time-consuming readjustments.

Indifference curves are permitted to touch axes, especially if one represents money. It is mentioned that the curves neglect indivisibilities and monotony and that they are assumed to be independent of the budget line—thereby neglecting conspicuous consumption, inference of quality from price, and expectational problems. It is explained that the height of a budget line depends on more than current income and that its slope equals the negative inverse of the price ratio. The algebraic derivation of consumer equilibrium uses not a specified utility function but any increasing function of the function.

It emphasizes that profit maximization is only one of a number of plausible axioms and indeed is an ambiguous one in a world with uncertainty and multiple interest rates. It explains that learning and equating  $MC$  and  $MR$  are time-consuming and expensive—and anyway may not maximize stockholders' wealth when there are discontinuities or unmet second-order and global conditions or when the producer must precommit himself or worry about entry or reputation. It recognizes that the more concentrated side usually admin-

isters prices, not quantities, and explains why. It shows that a budget maximum or an interest charge on additional outlays converts  $MRP = MFC$ , etc., into limiting cases.

It recognizes disagreement about whether returns to scale eventually diminish. It mentions rising at-plant input costs and internalization of external benefits. It distinguishes between plant and firm, between types of integration, and between instantaneous rate of output and hours of operation per year. It scallops or steps  $MC$  when output is increased by setting to work another group of machines, another shift, or another plant. It does not say 2.5 ( $K + L$ ) exhibits diminishing marginal products. It distinguishes discretionary fixed costs (e.g., insurance) and wholly fixed costs (e.g., bond interest). In counting basic solutions to linear-programming problems, it includes corner points on the axes.

Its conception of industry performance includes not only long-run equilibrium scale and price-cost relations but also progressiveness, product suitability, unethical practices, etc. It does not regard variety as opposite to standardization (e.g., of clothing sizes) and equivalent to advertising or say that nonprice and price competition function the same way.

It subdivides oligopoly, perhaps using Bain's types of concentration curves, does not say that what is true of two sellers extends to three or more, does not equate numbers with competitiveness, and does not say the antitrust laws maintain many firms per industry. It reconciles an assertion that oligopoly prices are rigid with an (erroneous) assertion that a kinked demand curve makes price increases likely when demand grows, and also with an assertion that price leadership (which irons out the kink) is common. It does not, after Oxenfeldt's analysis, repeat that barometric leadership merely establishes the prices that would be set by competition. It indicates the obstacles to joint maximization. It explains bilateral monopoly equilibrium and indicates its importance for bargaining associations and antitrust.

It does not equate pure competition with efficiency. It does not extol  $P = MC$  regardless of margins elsewhere. It recognizes that distance, delays, ignorance, and immobility can change every conclusion. It indicates that easy entry may produce cycles of entry and exit. It does not say that no incentive to enter exists when profits are small for the group. It distinguishes between liquidation of a company and departure of its capacity. It does not emphasize constant demand (and zero profits) to one farmer and varying prices to his industry. It explains how prices change if no one has any bargaining power. It mentions the surprisingly useful theory of price and production over space.

It recognizes that theories consist of axioms and theorems, together with a purview of circumstances wherein the implications of the axioms are deduced. It emphasizes that theorems (e.g., the substitution effect for a "consumer" is negative) are established logically—and therefore may be false empirically. It understands that a theory, however approximate, is scientific only if it is tested against facts and progressively modified to enhance predictive power, and therefore descriptive or normative usefulness.

Some of these desiderata are still fond hopes for the profession and are, consequently, not helpful in choosing among textbooks. On none of them, however, does Watson's book measure well. Teachers who now assign a text such as Baumol's *Economic Theory* would find Watson's work less comprehensive, less intensive, less rigorous—and longer.

On the other hand, teachers who want to avoid derivatives and who now use a careful but simple text such as Leftwich's *Price System* in their "intermediate" theory course might possibly find Watson's book a serious contender. It has broader coverage, together with attempted applications, occasional mathematical notes, careful printing, and helpful diagrams, summaries, exercises, and references.

STEPHEN H. SOSNICK

**Economic History; Economic Development; National Economies**  
*Structural Interdependence and Economic Development—Proceedings of an International Conference on Input-Output Techniques, Geneva, September, 1961.* Edited by T. BARNÁ WITH W. I. ABRAHAM AND Z. KENESSEY  
New York: St. Martin's Press, 1963. Pp. x, 365. \$15.00.

*Input-Output Tables—Their Compilation and Use.* Scientific Conference on Statistical Problems, Budapest, 1-5 June, 1961, Branch A. Edited by O. LUKÁCS, GY. CUKOR, P. HAVAS, AND Z. ROMÁN; translated by L. Várady.  
Budapest: Publishing House of the Hungarian Academy of Sciences, 1962. Pp. 292. \$8.50.

The most fascinating aspect of input-output analysis and its kindred branch of economics, mathematical programming, lies in the fact that concepts and problems form a common universe of discourse across Western and Collectivist economies. This is increasingly so as the interest in Western I-O analysis has swung toward development planning, as the first volume above signifies.

The volume edited by T. Barna reports on the third of periodic major Western conferences on I-O work. This 1961 Geneva conference was preceded by the 1951 meeting at Driebergen, where theory was dominant, while in the second, in 1954 at Varenna, computational procedures were important. The volume edited by O. Lukács, reporting on a Budapest conference held almost simultaneously, is also the third in line, the previous Warsaw and Berlin meetings having been devoted to I-O and socialist planning. Though there is great commonalty of ideas and problems across the Iron Curtain, there was little interchange of personalities at these conferences; of the 17 papers at Geneva, two were by economists from the Collectivist countries, and a single Western contribution appears among 21 papers in the Budapest volume.

Before embarking on a detailed survey, the general impressions left by these volumes may be noted. First, the enormous growth in the 1950's in work of an I-O nature—conference attendances given by Barna in the Introduction are one guide, and another is the great range of countries mentioned through-

out both volumes. Second, while the first I-O work began in Soviet Russia in 1923-24 (and Leontief published a discussion on this work in 1925), it seems the West has now gathered pace, and its work and discussion of many technical problems in I-O are now more advanced (the sputnik effect again). This is evidenced, looking at work done, by the fact that I-O tables for most of the Eastern European countries other than Russia were not in preparation until the end of the 1950's, while, of course, they were under way in the United States and in several European and Commonwealth countries in the 1940's (see the useful table in the Budapest volume, p. 49). Still on the relative rate of advance, when we turn to technical problems, it is noteworthy that many of the difficulties for future consideration noted by Kenessey in the Budapest volume are actively and adequately discussed in the Geneva papers. The third general impression is the increased interest in I-O for planning (in the West, that is), but the decline in interest in both areas of the world in computational problems (due partly to computers, partly to greater division of labor—economists leaving computation to computer departments). Fourthly, there is now an easy marriage between I-O and programming in its various forms, authors in both volumes slipping between one approach and another and considering "mixed" techniques.

Neither of these volumes can be appreciated without prior knowledge of I-O analysis and, at least, *linear* programming. The knowledge that a reader requires is essentially the following. First, the different degrees of "openness" that an I-O system can possess with regard to household operations, foreign trade, government operations; e.g., some or all of household supply of labor and purchase of products can be endogenously included. Several disputes in the volumes turn on this issue, e.g., in the first volume, that between Fox, Sengupta, and Day. Second, the problems of coefficients: aggregation, average versus marginal values, actual versus forecast values, and particularly changes over time. The time-change problem clearly assumes great importance when attention is focused on economic development, because growth through technical change is change in the parameters, which technically it is highly convenient to assume constant. Third, the essential difference between I-O and L-P, which can be understood from a childish example: in the "production" of car mileage using two factors, gas, and engine wear, I-O corresponds to a one-gear car, L-P to a choice of gear-ratios (each using different combinations of gas and engine wear per mile). Thus only in L-P does the question arise of choosing a gear to maximize mileage for given supplies of gas and engine or minimize inputs to achieve a stated mileage. And only in L-P, when the optimum gear is determined "centrally," does the question arise of using prices to guide "decentralized" car-drivers to choose the appropriate gear. Fourth, the basic distinction between current or flow-flow relations and capital stock-flow relations (dynamic I-O tables) must be understood.

Thus forearmed, we can look at each volume in more detail. Barna's Introduction mainly discusses the broad questions already covered here. No collection of Western I-O papers would be complete without a contribution from Chenery, and he begins with a demonstration (founded on an earlier article

in this *Review*) of how interindustry use of product grows more than proportionately to total production as per capita income increases. As Ghosh, later on in the volume, reminds us, we need to remember the effect of classification here. If the economy does consist of "islands" of production, you get zero or great interindustry flows according to whether sectors coincide with the islands or cut across them. Chenery's graph is partly to refute a view that I-O is inappropriate in less-developed economies—characterized by a paper of this reviewer—a misunderstood paper (also used by Eleish later) which in fact considers the *best* use in an underdeveloped country for extremely scarce statistical resources (in fact, *one* statistician in Tanganyika in 1956; compare the entourage there today!). Chenery is very good on a suitable mix of I-O and L-P for development planning and on the inadequacy (because of no recognition of interdependence) of the long *QJ.E.* discussion on Investment Criteria for Less-Developed Countries.

The remainder of Part I (Models of Economic Development) contains a paper by three Polish economists and papers by Mather of India, Fox, Sengupta, and Day. Each touches on several issues, but the dominating themes (in order) are the problems of change of technical coefficients in the growth process, independent "islands" (U.S. agriculture?) which need not be integrated in the I-O scheme, and prices and allocation (when programming is introduced).

Part II of the Geneva book is devoted to a relatively new area, regional I-O, a little off the line of the main theme of the book, underdevelopment and development planning, especially as all the papers—by Isard and Smolensky, Leontief and Strout, Hirsch, and a note by Leibling—refer solely to the United States. Still, they do show what a useful addition regional I-O can be to national planning to tackle regional underdevelopment, though applied to less-developed countries, "regional" activities would probably need to be drawn tribally or racially. The Leontief paper is much more technical than the one by Isard and, among other things, is a great exercise in "subscription."

Part III opens with a long essay by Nemchinov (the Russian Chenery, I gather from the Budapest book). This is about Soviet statistics, Soviet planning, Marxist theory, and so on; very little really about I-O. Presumably it would have been difficult for the editor to do anything about this, and we do have to remember that the Collectivist economists conceive I-O as a small cog in a much wider scheme of planning and control than we do. The French contribution, from Delange, in contrast, is confined to the French official I-O tables and deals not at all with French planning, where perhaps a little on the role of I-O therein would have been interesting. Eleish and Bruno, on Egypt and Israel respectively, give very good accounts of the special problems of I-O in less-developed countries. A special feature of the first of this pair of papers is the discussion of the different treatment of competitive imports and noncompetitive imports in I-O analysis used in programming industrialization, and of the second, a test of development-plan forecasts with subsequent actual happenings. Balboa gives a useful account of E.C.L.A. work on I-O in selected Latin American countries.

The final section, Part IV, deals with statistical problems: the Japanese contribution demonstrates how the labor coefficient varies considerably with size of firm, causing difficulty in aggregating over same-product sectors in economies with traditional and modern production methods. Anne Carter deals with the inconsistency of using capital-coefficients implying new techniques simultaneously with extrapolations of existing flow coefficients implying old techniques. Sevaldson and Watambe separately deal with changes in coefficients at an advanced level. The volume concludes with an interesting discussion of the pros and cons of a U.N. standardized scheme for I-O collection similar to the System of National Accounts (the base is already laid with this and the U.N. International Standard Industrial Classification of All Economic Activities). Added to the existing great variety within the endogenous part of the I-O tables will be a steady loss of the current uniformity in final demand columns and primary input rows as these are broken up for endogenous inclusion (e.g., labor inputs by expenditure patterns, savings habits, family size, social class?). In a word, standardization would permit international comparisons and encourage international discourse, but may limit specific national usefulness and would stultify creative change (the price of the S.N.A.!).

The Budapest volume is a more systematic account of the construction and use of tables in most of the Eastern European countries, but it does seem only on the verge of many technical problems tackled squarely in the Geneva book. I shall try to draw out the essential differences in I-O in the Collectivist economies compared with others. I-O is much more of a small piece of wider planning machinery in Eastern Europe, as already mentioned. Basic I-O statistics are better in Collectivist economies since firms are sympathetic to the needs of State planning (a claim made at Budapest). Prices used for values in I-O are not market prices but administered ones, so there arises the possibility of calculated "shadow" prices (if programming is added to I-O) actually being put into use in the Collectivist economy. Greater use of engineering or planned coefficients rather than actual ones occurs. The construction of the table in Collectivist economies is somewhat different from Western methods to accord with Marxist theory, e.g., the distinction in the endogenous part of the table between productive and nonproductive sectors; primary inputs classified so that their remuneration corresponds to the "wage-fund," "surplus product," etc. Note the significance of all these differences for the world-standardization discussion.

I am inclined to say that the Geneva volume is for I-O students, the Budapest one for students of Marxist economies. It is difficult to allow for one's own outlook: the Budapest volume has been adequately translated into English but it still reads like a foreign language to someone not steeped in Marxist economic terminology. Perhaps a Soviet economist would say comparable things about the Geneva book, but it is undeniable that the only *explicit* propaganda appears in the Nemchinov paper in Barna's volume and at several places in the Budapest volume. In spite of this, I-O retains its pre-eminent place as that part of economics with the widest political and geographi-

cal spectrum—a World Government would know where to begin its economic statistics.

DOUGLAS DOSSER

*University of York*

*Economic Development: Past and Present.* By RICHARD T. GILL. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. vii, 120. \$3.95.

This book is one of nine volumes included in *The Foundations of Modern Economics* series, designed to serve the text requirements of the basic economics course. The stated purpose of the series, which is under the editorship of Otto Eckstein of Harvard, is to provide more flexibility in the choice of topics included in a first-year course through brief, self-contained volumes written by specialists in each field. This approach constitutes another assault on the firmly entrenched introductory tome in economics, reflecting perhaps a growing disenchantment with the overstuffed conventional text.

This volume under review presents a meaty introduction to the field of economic development for students and the general reader. It covers in six chapters the "General Factors in Economic Development" (population, resources, capital); "Underdevelopment, Growth and Getting Started" (Rostow's stages, classical theory, vicious circles, big push, etc.); "Beginning of Growth in Economically Advanced Countries" (impact of the Industrial Revolution); "The Growth of the American Economy"; "The Problems of the Underdeveloped Countries," (meaning of, demand for, obstacles to, required scale of development); "Alternative Approaches—India and China." Emphasis is on historical description and review of institutional factors contributing to the widening gulf in international living standards. The problems of getting started, the evolution of technology and its impact on the late-comers, including the United States, are ably treated. Comparative statistics, charts, and tables support the exposition. The last two chapters, where one would expect the perspectives and modern tools to be applied, do not quite live up, in terms of analysis, to the build-up of the first four.

Some familiar concepts and historical themes might have been sacrificed in favor of dealing in depth with capital-output ratios, absorptive capacity, marginal savings, shadow prices, underemployment, *n*-achievement, and other need and aspiration criteria. Most of these terms in fact, even if implied in some of the discussions, are absent from the vocabulary of the text. Particularly where they have quantitative significance, these concepts would have provided a logical foundation—supplementing the historical and descriptive material—for a more problem-oriented and analytical approach to the case examples of India and China in the last chapter. How do the Indian and Chinese planners calculate specific capital-output, savings, and capital-import ratios required for generating per capita income gains to meet the demands of self-sustained growth and regional and international comparisons? Why have domestic savings ratios in India remained so unimpressive, and what devices can the planners suggest for increasing them, as well as reve-

nues from domestic taxation, so as to reduce the heavy dependence on foreign capital? What are the eclectic issues which complicate the population variable in the growth equation? Analysis of basic operational factors gives the student some appreciation of the concrete tools and dynamic planning methodology currently being applied to gauge and forecast development requirements.<sup>1</sup>

The author also stresses the usual "capital poor" status of the underdeveloped areas, but more might have been said to show that they are poor in markets, innovation, entrepreneurs, administration, and motivation. In the reviewer's experience, the capital-shortage thesis needs qualification where capital availability is a lesser need than locating worth-while projects and organizing and motivating the local manpower to launch and administer them. In some areas, ten or more aid-giving countries and agencies, and even indigenous and foreign private capital, are seeking outlets simultaneously. The capital is there, but the proper feasibility groundwork is inadequate. Nor is it a question of absorptive capacity only, for this is expandable. More probing of these bottlenecks would have added depth and currency to the discussions.

A condensed coverage cannot be expected to please all of the diverse preferences of pedagogues, who will, in any case, supplement as they see fit. The omissions elaborated will not be missed by the general reader. Some may even prefer to add their own problems and analytics. It is more important for an introduction that the major perspectives and theses are here to inform and challenge. In this respect, this well-written treatise succeeds commendably.

RICHARD J. WARD

Long Island University

<sup>1</sup> The level prescribed for this book precludes application of Harrod-Domar, Cobb-Douglas, or Schumpeter-type growth models or functions, yet the student needs to supplement the static knowledge with the dynamics of such model building.

*Histoire économique: XIX<sup>e</sup> et XX<sup>e</sup> siècles.* 2 Vols. By J.-A. LESOURD AND C. GÉRARD. Paris: Armand Colin, 1963. Pp. 292; 372. F 19.80; F 24.

The appearance of a new introductory textbook in a foreign language is not often of direct concern to U.S. economists. But in the field of economic history there are so few books which are both modern and sufficiently broad to serve as introductory texts that such linguistic provincialism is inappropriate. The present book, covering the period from 1750 to the present, should prove useful both to teachers and to students in first courses in economic history who can read French.

The authors, J.-A. Lesourd and C. Gérard, are, respectively, teacher of history at the University at Nancy and teacher of history and geography in classes preparatory to the *grandes écoles*. Much of the most interesting French work in economic history has been done by historians and geographers, and I feel that the book gains, on balance, from following this tradition rather than that of political economy.

A major virtue of this text is its form. It is attractive, easy to read, and convenient to use. There is an abundance of charts, tables, graphs, maps, and dia-

grams, usually appropriate and often imaginative, some of which serve to illustrate concepts as well as to present factual material. In addition there are appendices on the presentation of statistical material, on weights and measures, and general and chapter bibliographies. Few non-French works are mentioned, showing that provincialism is not limited to Anglo-Saxon authors.

Lesourd and Gérard have chosen to be comprehensive rather than selective in their coverage, relying on pithy generalizations and *caveats*, as well as occasional forays in depth as defense against the perils of superficiality. On the whole I think that they have succeeded well. The extended introduction touches almost every field of economics insofar as it can shed light on the history of the nineteenth and twentieth centuries. The chapter dealing with the history of economic doctrine emphasizes social philosophers rather than theorists (the chronology omits Wicksell, Marshall, Böhm-Bawerk, and Schumpeter, *inter alia*, but includes French writers whose intellectual importance is at least open to doubt). The treatment of institutions (firms, banks, monetary systems) is particularly good, whereas the chapters on prices and cycles are marred by ambiguity and flaws in the data. The authors use the concept of "real prices," due to Fourastié, with prices weighted by average hourly money wages, thus biasing price series downward for the nineteenth century. This in turn leads them to characterize the period as one of downward long-term trend (in their treatment of cycles), with no clear distinction made between movements in prices and changes in the level of activity.

In the chronological part of the book, the authors have chosen to present a rather detailed picture of the world economy at certain times (1750, 1850, 1913), and to treat the intervening periods sector by sector. This approach provides a nice balance, without undue concentration on particular countries in the "snapshots," and yet opportunity to give more detailed accounts of particular aspects of French, European, or American experience.

In the last part of the book the story is brought up to the present time, in this reviewer's opinion, with distinctly less success. Here the source materials are incomparably richer, and the authors are not able to carry off the herculean task of digesting so much scholarship and analysis. Economic errors and unsupported or questionable arguments become more frequent, while the treatment of factual material is more along the lines of economic geography and relies considerably on raw statistics. Nor is the sketchy coverage of problems and theories of underdevelopment adequate either as a substitute for, or a complement to, work on that subject proper.

As regards the historical discussion, I would argue with Lesourd and Gérard on a few specific points. In their treatment of French agriculture they imply that the extension of acreage planted in wheat during the nineteenth century represented progress and rationalization (p. 298). In fact, it was the result of protection and local autarkic efforts. The considerable work done, in the United States and elsewhere, on the relationship between French economic retardation and entrepreneurial attitudes (the family firm, the role of banks in industry, etc.) is largely ignored. As regards England, the mid-century period of high-farming is not mentioned. Nor is the failure of British industry to progress in new lines given its due in accounting for the relative decline of Great Britain toward the end of the century.

This is an interim synthesis, as the authors and publishers point out. It suffers in spots from hasty writing, from occasional specious clarity in formulating vague concepts, from a slight predilection for numbers at any cost, even when adequate data are not available, and from touches of implicit Marxism. But it is a useful, readable, and courageous effort. In fact, the authors have accomplished something of a *tour de force* in combining a well-written, concise, and coherent text with the presentation of a large body of factual material, much of it not easily available to the student. A later version, incorporating data and analysis becoming available as the result of current research, and ending in 1918 (or 1939), would be of considerable help to students and teachers interested in economic history in the context of economic growth, theory, and quantitative methods.

PAUL M. HOHENBERG

*Stanford University*

*Profile of Michigan—Economic Trends and Paradoxes.* By STEPHEN P. SOBOTKA WITH T. A. DOMENCICH. New York: Free Press of Glencoe; London: Collier-Macmillan, 1963. Pp. xvii, 174. \$4.95.

This book is a monumental example of the misuse of economic theory, statistics, and mathematics. It might well be read by every graduate student as an example of how not to do economic research.

The starting point for Stephen Sobotka's analysis is the apparent paradox of unemployment amid plenty in Michigan: high wages and high income per capita are accompanied by higher rates of unemployment than in nearby industrial states. At least at the time the study was done these conditions prevailed. Sobotka argues that the only reasonable explanation for this paradox is that high wages have caused business firms to substitute other factors of production for labor, thereby causing high rates of unemployment. Calculation of "elasticities of substitution for labor" shows that in the transportation-equipment industry, which is very important in Michigan, it is relatively easy to substitute against labor. These calculations indicate that a 1 per cent increase in relative wages in the transportation-equipment industry in Michigan results in a 2 per cent decline in employment in the industry. The policy conclusion is obvious: Sobotka advocates "public policies that will erode the power of unions to raise the wages of their members and thus cause other competent workers to be unemployed."

The uniqueness of Sobotka's research lies not in the argument he makes, which is almost as old as economics itself, but in his efforts to quantify the substitution against labor and compute elasticities of substitution by industry. The procedure is described in Chapter 4, which had been published independently, and in an article by Minasian, who apparently worked with Sobotka on the project. It is based on the Arrow-Solow production function.<sup>1</sup>

<sup>1</sup> Stephen P. Sobotka, "Michigan's Employment Problem: The Substitution Against Labor," *Jour. Business*, April 1961, 34, 119-28; Jora R. Minasian, "Elasticities of Substitution and Constant-Output Demand Curves for Labor," *Jour. Pol. Econ.*, June 1961, 69, 261-70; Kenneth J. Arrow, Hollis B. Chenery, Bagicha Minhas, and Robert M. Solow, "Capital-Labor Substitution and Economic Efficiency," *Rev. Econ. Stat.*, Aug. 1961, 43, 225-50.

It is possible to analyze Sobotka's method, but only by going beyond Chapter 4 to Minasian's article. At no point in the book are the critical mathematical-statistical procedures described and the crucial calculations given. This is quite inexcusable, for the unsuspecting reader is asked to accept on faith methods and calculations which close examination shows to be wrong.

The first mistake is an economic one. The "elasticity of substitution" on which the whole analysis rests turns out to be only a mathematically inverted measure of labor productivity. In Sobotka's words:

The elasticity of substitution was computed by a series of regression equations in which labor input, in either physical or money terms, was the dependent variable and average hourly earnings the independent variable. *To allow for interstate differences in scale of operations, the labor inputs were deflated by value added* (p. 60, my italics).

The usual measure of labor productivity is:

$$\frac{\text{value-added } (V)}{\text{labor input } (L)}.$$

When it is regressed against wage rates, a positive relationship appears. The higher the wage rate, the higher is productivity ( $V/L$ ). What Sobotka did was to reverse the relationship to:

$$\frac{\text{labor input } (L)}{\text{value-added } (V)},$$

and, *mirabile dictu*, got a negative relationship. Instead of recognizing it for what it was—a mathematically inverted measure of productivity—he thought he had found a measure of the elasticity of substitution against labor.

Analysis of Minasian's article, in which the method is described in more detail, confirms this point. Minasian's equation (2) was the basis of the calculation of "elasticities of substitution":

$$\frac{W \cdot L}{S} = A W^{(1+n)}$$

where

$W$  = price of labor

$L$  = quantity of labor

$S$  = value-added

$n$  = elasticity of demand for labor with respect to its price

$A$  = a constant

Dividing through by  $W$ , it becomes:

$$\frac{L}{S} = A W^{(n)}.$$

Solving for  $W$ , it becomes:

$$W^n = A^{-1} \left( \frac{S}{L} \right)^{-1}$$

which is equivalent to

$$W = A^{-1/n} \left( \frac{S}{L} \right)^{-1/n}$$

This equation tells us, in graphic terms, that there is a straight-line relationship between wage rates and productivity ( $A$  is a constant), and curvature is introduced by substitution against labor ( $n$  is an exponent). The assumptions, inherent in the mathematical formula used, are highly unrealistic in themselves. However, if  $n = -1$ , the equation becomes:

$$W = A \left( \frac{S}{L} \right)$$

which is nothing more than saying that wage rates are functionally related to labor productivity.

Since  $n$  is Sobotka's "elasticity of substitution against labor," it is vitally important for his argument to show that his figure for the transportation-equipment industry is significantly different from  $-1$ . Otherwise, the relationship between wages and employment is all explainable by the productivity of labor and none of it by substitution against labor.

Here Sobotka (and/or Minasian) made a second mistake, this time in statistical technique. Using data for the transportation-equipment industry from 18 states for a single year, the elasticity of substitution for labor was calculated at  $-2.04$ , with a standard error of  $.49$  and an  $r^2$  of  $.22$ . According to my calculations this elasticity of substitution is just barely significantly different from  $-1$  at the 5 per cent level. But it would not be so with only 17 observations. A question should immediately be raised about the homogeneity of the 18 observations. Are they from the same universe? Are they observations of the same family of phenomena? For the purposes of this study they are not. The transportation-equipment industry in Michigan produces automobiles primarily; in California, aircraft; in another state it might be ships or railroad equipment. Within the automobile industry itself, design and tool and die operations are heavily concentrated in Michigan, while in other states assembly operations predominate. In a case like this, when the statistical test shows borderline significance at best and the data are of doubtful homogeneity, the proper technique is to conclude that statistical significance has not been proved. The figure for elasticity of substitution for labor cannot be considered significantly different from  $-1$  when a close look is taken at the nature of the observations on which it is based. The proper conclusion to be drawn from Sobotka's mathematics and statistics is that high wage rates in Michigan are associated with high levels of labor productivity.

This does not mean that high wage rates in Michigan have been of no

importance in causing employers to substitute against labor. But it does mean that Sobotka has (a) failed to prove that they have been and (b) failed in his effort to quantify the effect.

The study has other faults. The average levels of unemployment shown for Michigan are high primarily because of conditions in 1956-58 and not because of consistently high levels throughout the period studied. Although the last data analyzed are for 1958, the author continually writes as if the trends shown still persisted at the time of publication. One would hardly suspect that in 1963 the rate of unemployment in Michigan was well below the national average and below that of the surrounding states.

Uncritical reliance on statistical techniques has led Sobotka to ignore some of the basic causes of Michigan's economic problems: the tendency of any geographically concentrated industry to decentralize in an expanding economy; the effect of the Supreme Court's basing-point decision on location of metal fabricating plants; the large decline in defense contracts in Michigan as national defense shifted to missiles; the excessively high labor participation rates in Michigan in 1953-55; the self-generating and competitive nature of automation once it has begun in an industry. All of these factors were discussed in the literature on the Michigan economy at the time Sobotka was working on the problem, and they should not have been ignored.

Sobotka's fiasco is a classic example of a methodological trap that is always ready to snare the unwary economist. Mathematical and statistical techniques can become an end in themselves, obscuring the underlying economic reality which should be the central focus of attention. This is what happened to Sobotka, with disastrous results.

### **Statistical Methods; Econometrics; Social Accounting**

*On the Accuracy of Economic Observations.* 2nd ed., revised. By OSKAR MORGENSTERN. Princeton: Princeton University Press, 1963. Pp. xiv, 322. \$6.50.

The first edition of this book, which appeared in 1950, will be familiar to many readers. The present edition is substantially enlarged and brought up to date. Part I discusses the nature of economic data, detailing at some length both the sorts of failings to which economic data are subject and the sorts of misuse to which they are commonly put. Part II consists of seven chapters, each of which discusses a particular type of statistics, namely foreign trade, prices, mining, agriculture, employment and unemployment, national income, and growth and growth rates. Finally, there is a short chapter on the orientation of future research.

In his concluding chapter Professor Morgenstern is careful to state that "there was no intention to make a chamber of horrors, nor to belittle the efforts of the many good workers to whom our data are due." Unfortunately, an atmosphere of hopelessness does pervade the book. To this reviewer, how-

ever, the state of economic statistics does not seem to be quite as black as it is pictured here.

The types of error with which Morgenstern is concerned run the gamut from failure of the data to measure the concept they are supposed to (often because the concept is itself imprecisely defined), through mishandling of statistical techniques by the makers of the statistics, to deliberate falsification, and finally, such factors as machine errors in the processing of data. His concept is thus far broader than what is usually thought of as statistical error.

Morgenstern's conclusion, with regard to all of the types of data examined, is that margins of error are extremely wide, and that errors are not likely to be offsetting. Even biases in the data can not be relied on: for instance, changes in national income are pictured as little, if any, more reliable than the absolute levels of national income. His methods of arriving at these conclusions are rather hard to pin down; for the most part, they seem to come down to looking at a set of data to see if it looks reasonable—and what is reasonable varies from page to page. The BLS is chided for never revising its figures, but the OBE's revisions are used against it as evidence of error. He regards the greater frequency of revision in postwar as compared to prewar data as evidence that the statistics are not getting any better; but later he views with alarm the fact that figures ten years old are still being revised.

It is in his prognosis of the future that Morgenstern's pessimism is most acute. In discussing what can be done about the present parlous state of affairs, he relies mainly upon a hope that things will get better by-and-by, as the level of economic education and sophistication of people in general rises. His concrete proposals appear to be three: (1) discard data based on lies; (2) prevent government agencies such as the Council of Economic Advisers "from presenting to the public economic statistics as if they were free from fault"; and (3) "insist that economic statistics only be published together with an estimate of their error." He does not, however, tell us how to achieve these ends. Nor is it entirely clear how far he really means to push them. Few economists would disagree with him when he argues that changes of one- or two-tenths of a per cent in price indexes have no meaning; on the other hand, few would follow as far as his statement that quarterly national income figures are "grotesque." Does he really mean that every time the Council of Economic Advisers prepares a speech for the President, they must either use such language as "the gross national product rose \$10 billion (plus or minus \$10 billion)" or else say nothing at all about what is happening to economic activity? He writes rather sadly that the answer to critiques such as his is always, "Yes, but the data we have are better than nothing at all"—and I do not think that he really means to disagree with this.

It is Morgenstern's third recommendation that is likely to give the average producer of economic statistics the most qualms, and at the same time most seriously to mislead the unwary or unsophisticated user of data. To illustrate from the discussion of national income statistics, Morgenstern quotes (as if they applied to present-day OBE national income accounts) some remarks made by Simon Kuznets in his 1942 book relating to data of an earlier period compiled by the National Bureau, to the effect that the national income was

subject to an error of 10 to 20 per cent. Since 10 to 20 per cent of \$500 billion is \$50 to \$100 billion and the observed annual changes in gross national product run much less than this, Morgenstern regards any discussion of even the direction of annual change, much less its magnitude, as idle. It is just here that the danger of attaching simple-minded estimates of errors lies. Despite Morgenstern's dismissal, the estimates *are* subject to the same general biases from year to year, and the errors to be expected in the change figures are less than those in the absolute figures. No one really cares what the error in the absolute magnitude of the gross national product is, because no one has yet thought up a way to use this figure in isolation. What really would be needed, to satisfy the need Morgenstern feels, would be the computation of estimates of error for all of the possible combinations and comparisons which anyone might wish to use. The statistical agencies are obviously justified in arguing that any such performance is beyond the limits of common sense, and that the only practical solution is for the user to familiarize himself with the sources and methods at least enough to make his own judgment about the validity of the data he is using in the particular use he wishes to make of them. Admittedly, many users will not make the necessary effort, and there will be much misuse of the data—but this is likely to be much less harmful than the assignment of outrageously large error figures to all economic statistics.

NANCY D. RUGGLES

*Yale University*

*Linear Programming and Extensions.* By GEORGE B. DANTZIG. Princeton: Princeton University Press, 1963. Pp. xvi, 625. \$11.50.

It is now more than a decade since George Dantzig began the series of RAND papers that have culminated in this monumental treatise. The book covers the field authoritatively and has something for everybody: proofs for the mathematician, model formulation for the operations-research practitioner, computational techniques for the electronic-computer specialist, and network theory for Hungarians.

To an economist who is convinced that linear programming was really invented by Ricardo, this volume is bound to be annoying. Dantzig's interpretation of the simplex multipliers as competitive prices does not appear until Chapter 12—well after he has covered simplex computations, duality theorems, parametric programming, and given two alternative proofs that the simplex algorithm terminates in a finite number of steps. Incidentally, he succeeds in covering most of this ground without the use of matrix algebra.

No matter how blasé the economist's attitude toward computing techniques, he cannot afford to deny himself the pleasure and the educational experience of Chapter 23, where Dantzig explains the decomposition principle, his joint discovery with Philip Wolfe. Unlike the first Dantzig and Wolfe paper on the subject, this one is as much fun as a conversation between Pooh and Piglet. More than one coffee-hour will be whiled away in guessing at the identity of the renowned economist-consultant, F. M. Dalks. Maybe some of those coffee-hours will also be spent in debating just why the decomposition

principle is guaranteed to be convergent—even though it can be interpreted as decentralized planning with incomplete information at the center. What is the essential ingredient here that leads to convergence? With countercurrent flows of price *and* quantity information, it may be that D. & W. have invented the kind of friction that Dorfman-Samuelson-Solow had in mind when they remarked, "In competitive markets, as in pendulums, a little friction may be needed for stability."

Dantzig's book deserves to be widely read. The publishers are to be commended for having kept the price of this volume within reasonable limits.

ALAN S. MANNE

*Stanford University*

*Nichtlineare Programmierung.* By H. P. KÜNZI AND W. KRELLE WITH W. OETTLI. Berlin, Goettingen, Heidelberg: Springer Verlag, 1962. Pp. xiii, 221. DM 38.

Linear programming is concerned with the maximization (or minimization) of a linear function under conditions which are linear inequalities. These methods have been successfully used by economists in both theoretical and applied economics. But it is evident that the restriction to linear relationships cannot be considered anything but a very rough first approximation. Generalizations of the methods of linear programming for nonlinear functions meet formidable mathematical difficulties.

This is an excellent monograph on nonlinear programming. It is self-contained, and the first chapter includes the necessary mathematical theorems (matrices, vectors, linear equation systems, projections, quadratic forms, convexity). In the second chapter we have a short introduction to linear programming, where duality and the simplex method are stressed. The third chapter presents convex programming and the Kuhn-Tucker Theorem, which is of utmost importance in nonlinear programming.

The remaining chapters deal explicitly with theories and numerical methods proposed by various authors in the field. In Chapter 4 we have quadratic programming. The methods by Hildreth and D'Esopo are presented in the fifth chapter. This method uses the duality theorem.

The method due to Theil and van de Panne utilizes the complete description method (Chapter 6). Chapter 7 brings the method of Beale, which applied the somewhat generalized simplex method. Chapter 8 presents the method of Wolfe, which also uses the simplex algorithm, as do the method due to Barankin and Dorfman (Chapter 9) and the method due to Frank and Wolfe (Chapter 10).

Entirely different are the method of gradients (Chapter 11) and the method of projected gradients due to Rosen (Chapter 12). The degenerate case is also treated here. The famous multiplex method of Frisch (Chapter 13) and the method of permissible directions due to Zoutendijk (Chapter 14) are special cases of the gradient method. The capacity method of Houthakker (Chapter 15) is applicable to strictly convex quadratic programs under somewhat restrictive conditions.

The mathematical theory underlying these procedures is clearly presented,

and all methods are illustrated with the help of numerical examples. A very complete bibliography surveys the literature in the field (pp. 213-18).

This outstanding monograph can be recommended to economists and workers in operations research interested in the field of nonlinear programming.

GERHARD TINTNER

*University of Southern California*

*Introduction to the Theory of Games.* By EWALD BURGER. Translated from German by John E. Freund. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. vi, 202. \$10.00; text, \$6.00.

This is a very useful textbook or reference book for game-theory courses trying to provide rigorous proofs for the most important mathematical theorems without presupposing very extensive mathematical preparation. (But it does require some mathematical sophistication from the student or else some elaboration by the instructor of the rather concise mathematical reasoning.) As the author himself points out in the Preface, the book contains very little heuristic justification for the assumptions and definitions used; instead it concentrates on the formal mathematics. But for this very reason it is a very suitable supplement to Luce and Raiffa's *Games and Decisions*, which is very good in heuristic explanations for game-theoretical concepts but gives few rigorous mathematical theorems and proofs.

Ewald Burger's book discusses noncooperative games (the theory of equilibrium points, with some economic applications), two-person zero-sum games (including a section on infinite games), and cooperative games (including the Shapley value). Particularly useful is an appendix on Sperner's Lemma, with elementary proofs for the Brouwer and Kakutani Fixed Point Theorems based on this Lemma (though there are a few misprints in the proofs).

The discussion is clear, rigorous, and to the point. The English translation is competently done but, like many other mathematical texts, it uses grammatical constructions too involved for easy understanding. Some of the long sentences could have been broken up with a gain in readability, even if this had meant somewhat greater length.

In the opinion of this reviewer, in case of a second edition the size of the book could be usefully increased by including additional material. For instance, it would be helpful to discuss a few more computation methods for finding solutions and equilibrium points; the section on infinite games could be expanded to advantage; discussion of the Nash-Zeuthen model could be included, etc. But even as it is this volume is a very welcome addition to textbooks in game theory.

JOHN C. HARSANYI

*Wayne State University*

*Linear Regression and Its Application to Economics.* By ZDZISLAW HELLWIG; translated from the Polish by J. Stadler. New York: Macmillan, Pergamon Press, 1963. Pp. xii, 238. \$5.00.

Dr. Hellwig, a Polish econometrician and senior lecturer in mathematics and mathematical economics at the University of Wrocław, has written a manual which will interest both economic statisticians and students of in-

tellectual developments in Eastern Europe. Simple linear regression, because of its mathematical "complexity" and computational difficulty, has not been utilized to any great extent by Poland's applied economists. Thus, in addition to presenting a fairly standard treatment of simple linear regression, Hellwig introduces a number of techniques which substantially reduce the computations normally required in regression analysis.

One-fifth of the volume is devoted to demonstrating the importance of simple linear regression to policy-makers. The result is a somewhat haphazard introduction to standard microeconomic theory, placed in a stochastic framework. Hellwig argues that regression analysis can be useful to the State in the setting of equilibrium prices and norms of production, and in judging the effects of alternate policies on equity. Because the author does not introduce multiple regression explicitly, the discussion of the application of regression analysis to economic research is much more confusing than is necessary. While some of the material may be of interest to scholars concerned with the influence of conventional economic theory on Polish economic thought, the reader interested in the applications of simple linear regression to economic policy can omit this section.

The discussion of statistical methodology provides a useful summary of much of the standard literature, a report of some of Hellwig's own research, and a large number of computational illustrations drawn from the Polish economy. Among the topics covered are specification of the simple linear model, hypothesis testing and estimation of parameters, tests of bivariate normality and the linearity of the regression function, transformation of curvilinear regression, and the use of regression analysis in the estimation of trends. While the discussion is often sophisticated, there is a great deal of variation in quality. The author sometimes neglects to make assumptions explicit. In the section on hypothesis testing, for example, where the reader is assumed to be familiar with elementary set theory and orthogonal transformations, the level of significance is defined as "the probability of an event that we consider as practically impossible" (p. 147). The discussion proceeds without any further explication of the theory of hypothesis testing.

The section of most interest to empirical workers is Hellwig's description of the computationally simple two-point method (or the method of grouping) for estimating the parameters of regression functions. While these estimators are less efficient than least-squares estimators (although they are consistent and unbiased), they are very useful in situations where electric calculators are not available or where a quick estimate of the parameters is required. The two-point method has also been widely developed for "errors in variables" models, and as a result there is a large body of literature dealing with the problem of the optimal grouping of the sample.<sup>1</sup> This literature is largely ignored by Hellwig. However, his discussion serves as a good introduction to the two-point method.

The major difficulty with this short volume is that it attempts to serve too many purposes: it is at once an introduction to microeconomics and statis-

<sup>1</sup> A. Madansky, "The Fitting of Straight Lines When Both Variables are Subject to Error," *Jour. Am. Stat. Assn.*, March 1959, 54, 173.

tics, a source book for the research worker, and a compilation of some of the author's papers. In addition, the lack of an index greatly restricts its usefulness to research workers. The book does serve as a reminder of the availability of simple computational techniques which have been largely ignored by economists.

BERNARD SAFFRAN

*University of California, Berkeley*

*Statistics for Economics.* By WILLIAM I. GREENWALD. Columbus: Charles E. Merrill Books, 1963. Pp. xviii, 366. \$8.75.

This is a textbook on statistics, one aimed at the student of economics who would become acquainted with the "application of (statistical) methods and techniques" to problems encountered in economic research. It is a self-proclaimed cookbook which places emphasis on a wide selection of recipes rather than on principles of nutrition. Consistent with these objectives, it does not attempt or claim originality or innovation in statistical methodology.

One may quarrel with the basic intent of teaching the technical manipulations of empirical research apart from the often quite subtle logical foundations upon which interpretation is based. But, as this is not the first textbook to exhibit this tendency, this review will attempt to evaluate the text on its own terms.

While a cookbook may justifiably concentrate on the "how" of statistical methods at the expense of "why" or "when," it should not neglect other obligations. It should provide its purchaser with a useful reference for consultation after his statistics course is long past and largely forgotten. In this regard it should possess an extensive index, a selective bibliography for specific topics at the end of each chapter, perhaps a glossary of terms, symbols and formulae, and certainly an appendix containing tables of statistical functions and logarithms. *Statistics for Economics* contains none of these things. Its index is three pages plus seven entries long; it has neither bibliography nor footnote references to sources of more complete or authoritative information; there is no glossary and only five 10-entry "samples" from various tabulated statistical functions.

At 366 pages this book is much shorter than other candidates for "Cookbook of the Decade." This implies that either depth or breadth must be sacrificed. In his preface the author admits that he made a "judgmental choice" among possible topics, but the reviewer is impressed rather by the lack of selection displayed in the body of the text. The inevitable consequence of superficial explanation and analysis is equally evident. Moreover, six pages of "prime" space in the first chapter are devoted to the tired old subject of significant digits and the associated rules of thumb for truncating sums, products, etc. This is a topic that is virtually ignored, and deservedly so, by more encyclopaedic texts. The general problem of propagation and cumulation of errors in complex numerical manipulations is, of course, important; it is also very complicated. But it is clear that the errors cannot be avoided by a ruthless application of the ancient rules of thumb. In fact, re-

peated application of such rules in a series of calculations is likely to ensure failure of the computational checks the author also recommends.

The first 40 per cent of the book "covers" general statistics, running the gamut from tabular presentation to simultaneous equation estimation. The treatment is necessarily thin, but it is suprisingly weak precisely where a cook-book should excel. This text does not stress efficient calculation procedures, it rarely presents illustrative calculations in terms of "real" data, and it does not provide problems for student practice.

The next 50 per cent is devoted to methods of analyzing economic time series. The conventional topics of index numbers, trend-seasonal-cycle-random decomposition, and National Bureau cycle analysis are presented along with the more exotic harmonic analysis and autoregressive models. This section is endowed with more illustrative applications than the preceding section but, to compensate, motivation for the various techniques is supplied even more sparingly.

A short final section is given over to empirical forecasting. It presents a classification of types of forecasting methods (but gives no examples), provides some very general remarks about the inscrutability of the future, and describes the formulation and use of indexes of diffusion.

Professor Greenwald has properly avoided the role of inventor in statistical methodology but he has been more adventurous in English usage. His choice of verb for forming or specifying an hypothesis is invariably *hypothesize*. While this may annoy the reader, he reads on to see what happens when a verb is needed for taking or forming an expectation. (This, too, ends in disappointment since the need never arises.)

There are other minor defects but it is questionable whether the text would be much improved by remedying them. Sentences such as "Therefore to say that something is random is to say that it is probable and not haphazard since a haphazard sample can contain elements of regularity" (p. 75) are unnecessarily obscure. A suggested treatment for time series plagued with autocorrelation is to "Employ multiple regression and correlation in which time is included as a third coinciding *or lagged* variable" (p. 292, italics mine). These examples are extreme but not isolated.

To summarize, this text compares very unfavorably with others on the market in a number of important respects. It is superficial rather than selective and it is completely lacking in several desirable features. Its strong points are not sufficient to balance the faults and make it a reasonable alternative to available texts.

### Business Fluctuations

*The Chinese Inflation, 1937-1949.* By SHUN-HSIN CHOU. New York: Columbia University Press, 1963. Pp. xiii, 319.

The second major study to be published in the United States in recent years about the inflation in China from the onset of the Sino-Japanese War

in 1937 to the advent of Communist rule in 1949, this book warrants high praise on a number of bases. The subject has been thoroughly researched and has been analyzed with great care; judicious and skillful application of the tools of economic theory and economic history are in frequent evidence throughout. The generally tight writing and organization of the book reflect much perspiration by the author and positive professional inspiration of Shun-Hsin Chou and the numerous eminent individuals cited as having encouraged or assisted him.

There are eight substantive chapters. Following a brief introduction to the subject and consideration of "The Pattern of the Chinese Inflation," four chapters deal with inflationary pressures in the government, private, and international sectors. These deal with such familiar matters as government receipts and expenditures, private consumption and investment, foreign exchange and trade policy, foreign aid, the balance of payments, etc. The last three substantive chapters deal with "Bank Credit, Velocity, and Inflation," "The Redistributive Effects of the Chinese Inflation," and "A Comparison of the Chinese and Other Inflations," (Germany, Greece, and Hungary). The volume ends with an "Epilogue" and five appendices of a statistical and theoretical character.

Chou's conclusions resemble those of Chang Kia-ngau whose book on *The Inflationary Spiral, The Experience in China, 1939-1950* was published in 1958. This should not be entirely unexpected for Chou was associated with the Central Bank of China when it was under Chang's governorship, assisted Chang with his study, and in turn was assisted with his own book by some of the same economists and bankers who had contributed in various ways to Chang's. Chou finds that between 1937 and 1949 the increasing rates of increase in price and note issues reflected the ability of the inflation to perpetuate itself once the process was started. He also found, as one would expect, that the increasing amplitudes of the fluctuations in them were indicative of the inherent instability of the inflationary process; and also, not surprisingly, that the rising ratios of price changes to the increases in the note issues reflected the major role which the increase in the velocity of money circulation played in intensifying the inflation.

With the admitted advantage of hindsight, Chou states that the following monetary and fiscal measures would have contributed to the reduction of the intensity of the inflation in the short run: (1) budgeting of the government's outlay of domestic currency on a monthly basis rather than on an annual basis; and (2) the acquisition of the purchasing power required for the budgeted expenditures via tax collections, sales of government gold, sales of foreign exchange held by the government, sales of government properties, borrowing from the domestic market, and other "appropriate" measures. However, Chou concedes that while such a program would have contributed to reduction of the intensity of the inflation in the short run, it would not have offered a fundamental solution to the problem. The problem ultimately could have been solved, he says, only by a drastic expansion in China's production, the development of an effective means of increasing government revenue, and/or the curtailment of government activities. In the postwar years, he says,

"the Nationalist government had neither the strength nor the necessary environment effectively to pursue these objectives. Only peace . . . and an effective large scale foreign-aid program could have changed the situation. Up to 1949, neither was in existence" (p. 274).

This is a variation on a major theme in Chang's book to the effect that Nationalist China was a helpless victim of overwhelming circumstances; that had China somehow been able to halt the inflation, the Nationalists would not have collapsed in 1949, and ultimately not only would the Communists have been defeated but economic conditions would have been materially improved. Chang in his study puts it in stronger terms than does Chou: "Many historical forces contributed to the collapse of the Nationalist government . . . but the direct and immediate cause which overshadowed all other factors was undoubtedly the inflation" (p. 363). In my judgment, such views illustrate the extent to which excellent economists can get so engrossed with the trees of their subject that they are unable to recognize the rest of the forest. Specifically, Chou and Chang, as well as others, appear to have spent so much time analyzing the inflation as an influence on events and attitudes in China from 1937 to 1949 that they have not considered the extent to which the inflation was in turn a reflection and an influence of those same events and attitudes. In short, they do not seem to be as impressed as I am by the interaction of other economic and noneconomic factors on one hand and the inflation on the other.

In closing, it needs to be reaffirmed that, despite this difference of opinion, Chou's book is an excellent piece of work. Very competently done, it will be of great interest and use to economic historians, monetary and banking specialists, and China hands for many years to come.

### **Money, Credit and Banking; Monetary Policy; Consumer Finance; Mortgage Credit**

*A Study in Monetary Analysis.* By ASSAR LINDBECK. Stockholm: Almqvist & Wicksell, 1963. Pp. 306. SKr. 30.

Mr. Lindbeck's book can be described as consisting of three main sections, with the first two closely related and the third hovering over but not quite touching the other two. It is, in essence, an attempt to fuse the works of Patinkin, Bent Hansen, and Gurley-Shaw. On this account alone, it deserves attention as an ambitious work which was many years in the writing. It is meticulously, and at times tediously, thought out. It never quite gets off the ground. For the most part, it burrows deeply into the analytical complexities of its logical structure, pausing time and again to examine each particle of grain displaced along the way. And when the going gets rough, Lindbeck thoughtfully simplifies the model or examines only one or two of a seemingly infinite range of possibilities, leaving the rest to the reader's imagination or want of it. Despite the deadliness of its style, it is a book well worth reading.

and it should appeal both to the pure theorist and to the policy-oriented economist.

The first part of the book (Chapters 1 to 3) is concerned with some basic methodological problems and the microeconomic theories of the household and the firm. The influence of Patinkin is unmistakable and fully acknowledged. Indeed, Chapters 2 and 3 can be described as "Patinkin plus uncertainty." For example, in the theory of the household, using a two-period analysis, we are concerned with a household's decision to consume, save, hold various types of assets (money and government and private consols), and its choice between work and leisure. The analysis is, of course, based on preference theory and the absence of a money illusion. A preference function of 16 arguments is set up and, subject to a set of conventional budgetary restraints, the optimum position of the household is arrived at. Within this model, Lindbeck traces the effects of a change in the volume of asset holdings under conditions of uncertainty where the Keynesian precautionary and speculative motives for holding cash balances are specifically introduced. In Lindbeck's words, "The motives for holding assets are still stronger . . . if uncertainty is assumed not only for the *timing* of future payments and receipts, but also for the *values* of expectational entities—such as prices, wage rates, interest rates, and income" (p. 23). With this extension of the Patinkin model, liquidity effects are then introduced for a range of assets of different degrees of marketability. There are no surprises or startling conclusions in the chapter, but it does serve to clear the air and tidy things up a bit for the analysis to follow.

Chapter 3 applies the same approach to the theory of the firm. A preference function is set up with profits, cash balances, government securities, and debt as arguments. It is assumed that firms have an aversion for debt, with the firm seeking an optimum position with regard to profits and debt. The behavior function, therefore, has as its arguments relative prices, profit tax rates, and, in real terms, initial asset holdings (including debt), interest payments on assets and debts of the preceding period, and interest rates. In short, the traditional notion of profit maximization is expanded to include other goals as well. Within this format Lindbeck has a valuable analysis of the willingness of firms to borrow and the role of internal funds in decisions to invest. The firm, in other words, is assumed to attach a positive utility to profits and financial assets and a negative utility to debt, i.e., the firm will seek to realize its optimum position with respect to profits, liquidity, and debt. The supply of funds is represented as a step function as the firm moves along the curve from the use of its own internal funds (at an assumed opportunity cost) to alternate sources of credit at progressively higher interest rates. It is here that Lindbeck first introduces the distinction between credit availability and interest rate effects. This distinction plays an important role later in the book and a discussion of it will be postponed for the moment.

Having set up his meticulously constructed microeconomic models of the household and the firm, Lindbeck is now in the position to play games. But he is faced with a formidable problem in Chapter 4. He has 14 behavior

functions—five for the household and nine for the firm—with, all told, an incredible number of independent variables. Says Lindbeck, in a classic example of understatement, “A presentation of the properties of all these behavior functions by an analysis of the sign, and possibly the magnitude, of every partial derivative of each function would make extraordinarily boring reading” (p. 99). A much simplified model is then introduced with six markets (consumer and capital goods, money, government and private bonds, and labor), and two types of firms (“a consumer good producer that does not supply capital goods, and a capital good producer that does not supply consumer goods and does not demand (additional) capital goods”). Employing the technique of comparative statistics with the microbehavioral functions of the abbreviated model, a demand-supply analysis is used to gauge the direct effects of monetary and fiscal policy. Under direct effects, Lindbeck examines the impact of taxation on household income and on profits and the consequences of open-market operations. Autonomous changes in government and private behavior are also brought in to trace the channels through which the direct effects will flow. For the analysis of the indirect effects, the model is further simplified with the functions restated in aggregate terms. The resulting macromodel is then used to analyze the indirect effects of monetary and fiscal policy. The effects of certain parameter changes are considered and an attempt is made to determine, as far as possible, if a new equilibrium situation will be restored automatically. If the system proves to be dynamically unstable, then the role of government is brought in to counteract or eliminate the destabilizing factors. The parameter shifts examined are (1) a shift by consumers from cash balances to consumer goods, (2) a reduction of personal income taxes, (3) open-market purchases by the central bank, (4) a shift of the consumption function at the expense of either money balances or of lending, (5) an increase in the propensity to invest along similar lines, and (6) changes in productivity.

The most serious criticism that can be made of this chapter, and of the book as a whole, is the assumption that time lags in the policy variables simply do not exist. Lindbeck is much too absorbed with the mechanics of his general-equilibrium model to worry about the possibility that many of his policy variables may actually turn out to be perverse in their effects because of the lags involved. He is, of course, aware of this problem but dismisses it in one paragraph with the statement that “there is at present no generally accepted opinion about the length of these time lags, and about how the length varies between different business situations” (p. 167). One wonders if a lagged partial-equilibrium model would not have been more to the point.

Another shortcoming of Chapter 4 concerns Lindbeck's two definitions of an equilibrium situation: (1) where excess demand is zero in all markets of the model, and (2) where there is no tendency for prices to change. The second definition does not coincide with the first so long as zero excess demand is not a necessary and sufficient condition for price stability. Lindbeck's sympathies lie with the first definition, but as a concession to the “real” world he assumes that though prices may be sticky downwards, wage rates are

subject to a ratchet effect. It would have been more interesting, however, if a ratchet effect were assumed also for commodity prices and the second definition were then given its full due. In this event, the analysis of the role of government within the second definition would have been more relevant.

We turn now to the most important part of Lindbeck's book. Chapter 6 has to do with bank and nonbank financial intermediaries, and Chapter 7 with the availability of credit doctrine both in its European and U.S. versions. In Chapter 6, and as a welcome change after so much abuse, the tattered and battle-scarred colors of Gurley and Shaw flap briskly in Lindbeck's breeze. Much of this chapter is devoted to a careful and systematic analysis of the *credit* creation multiplier (as distinct from the *money* creation multiplier). Lindbeck sides with Gurley and defends him from his critics. He argues that nonbank financial intermediaries *are* "creators" of loanable funds and dismisses the arguments of Culbertson, Smith, and Aschheim. Perhaps an extended quote from Lindbeck would be in order (pp. 207-8).

(I)t has been (explicitly or implicitly) assumed . . . that the answer to this question is of relevance for the problem of the "desirability," from the point of view of the efficiency of monetary policy, of extending the system of cash reserve requirements to cover non-monetary intermediaries and not just commercial banks. The answer to the question who is a "creator of loanable funds" and who is not, depends, of course, on how creation of loanable funds is defined. In the traditional loanable funds theory, supply of loanable funds has been defined as saving + reduction in money balances ("dishoarding") + money creation. If "creation" of loanable funds is identified with "supply" of loanable funds, in the aforementioned sense, all types of behavior units can create loanable funds. . . . (However, a difference between commercial banks and non-monetary intermediaries, in the respect under discussion, is that the latter can create loanable funds only by dishoarding, whereas commercial banks can create loanable funds also by money creation. Some of the authors who have argued that non-monetary intermediaries cannot create loanable funds seem to have forgotten that intermediaries can dishoard, in the sense of increasing credit supply by reducing money balances.) Moreover when induced changes in liabilities of intermediaries are considered, even these kinds of credit institutes may, as we have seen, perform "multiple credit expansion," even though their liabilities are not usually used as a means of payment. Even in this sense, intermediaries can "create credit."

Within his model, Lindbeck considers the potentially destabilizing effects of intermediaries and their expansionary asset effect on the economy "(1) by shifts between money and private loans, (2) by shifts between government securities and private loans, and (3) by shifts between money and government securities." Next he considers control over the supply of *credit* via liquid-asset ratios, required cash reserves for intermediaries, and other selective controls. This chapter is well worked out and should serve to clear up many of the substantive and semantic confusions usually found in the treatment of financial intermediaries.

Chapter 7 is also well thought out and informative. Its discussion of recent

developments in monetary theory is excellent. Lindbeck begins by distinguishing between the U.S. and U.K.-Swedish versions of the availability of credit doctrine. The U.S. doctrine, as developed by Roosa and Sproul, emphasized the increased sensitivity of the financial sector to small interest rate changes and placed virtually all of its faith on the locking-in effect. Proponents of the availability of credit doctrine in the United Kingdom and Sweden, on the other hand, were more agnostic about the efficacy of interest rate changes and placed a greater reliance on liquid asset ratios, reserve requirements for intermediaries, and direct controls over the credit advances of all types of credit institutions. In short, the U.S. version of the availability of credit doctrine favored open market operations and discount rate policy to control the supply of *money* whereas most European adherents leaned more toward control over the supply of *credit* with a mix of direct as well as indirect financial controls. In effect, the difference between the two versions turned on the relative strength of the so-called locking-in effect. Concern in Europe was with the *composition* as well as the *volume* of loanable funds and this led them to "a much more interventionist political philosophy" than the Federal Reserve Bank of New York (not to mention the more conservative Board of Governors) would ever be willing to entertain.

By far the most valuable part of Chapter 7 is Lindbeck's distinction between the interest rate and availability of credit effects. From the lender's point of view, limitations in the availability of credit are explained in terms of the stickiness of interest rates because of (1) institutional rigidities, (2) good-will considerations, and (3) personal discrimination.<sup>1</sup> Two subcategories are developed where the supply of credit curve is of the conventional type and another where credit risks become so great that the supply of credit becomes perfectly inelastic. Lindbeck then distinguishes between a restriction in the availability of credit because of credit rationing (i.e., the amount by which demand exceeds supply) and a change in credit standards involving a leftward shift of the supply of credit curve. The former is largely a matter of personal discrimination whereas the latter is compatible with the allocation of credit via the market mechanism. From the borrower's point of view a step function of borrowed funds is introduced to describe the alternate sources of credit available to a borrower at increasingly higher interest rates. A tight-money policy results in an upward shift of the supply curve with the horizontal shortening of each step representing the decrease in credit availability (the credit availability effect) and the vertical displacement of

<sup>1</sup> In the United States a fourth reason can be given for the stickiness of interest rates, namely, *political*. The public debt and the size of consumer instalment debt would be the complicating factors. If 4 per cent can raise the ire of Congressman Wright Patman, 7 or 8 per cent should bring down the entire Congress! Lindbeck comes close to arguing in favor of an interest rate *ceiling*. Coupled with the familiar idea of an interest rate *floor*, the interest-rate-ceiling concept could be used to counter those arguments that talk about a theoretical or "effective" interest rate which would do the job. If the effective interest rate lay outside the institutionally feasible range of interest rate variation, owing to some insensitivity to small interest rate changes, the discussion and disagreements concerning the effectiveness of conventional monetary policy would be more meaningful and considerably more to the point. It is strange that this notion of an interest rate ceiling has been in large part ignored.

the supply curve representing the interest rate effect. Lindbeck, contrary to some writers on this subject, holds the view that both effects must be considered simultaneously. Whether or not one rather than the other predominates depends on whether a borrower is limited in the number of alternate credit sources available to him and whether he is already standing on the highest step with nowhere else to go. The remainder of the chapter explores selective credit controls and the arguments against large interest rate variations—most of which Lindbeck dismisses as exaggerated except possibly for the discriminatory impact of monetary policy on the smaller economic units, the effect of gross monetary policy measures on the distribution of income, and the possible effects of high interest rates on the rate of economic growth.

Chapters 6 and 7 make up well over 40 per cent of the book and are most probably an expansion of a much-mentioned earlier monograph by the author.<sup>2</sup> They have, however, a rather slight connection with the theoretical core of the book. Lindbeck has not, in my view, succeeded in playing the role of an eclectic by synthesizing Patinkin, Bent Hansen, and Gurley-Shaw—particularly with regard to the last. Yet it is a book that deserves to be taken seriously both from the theoretical and policy points of view.

STEPHEN W. ROUSSEAS

*New York University*

<sup>2</sup> Assar Lindbeck, *The "New" Theory of Credit Control in the United States*, 2nd ed., Stockholm Economic Studies, pamphlet series no. 1, Stockholm, 1962.

*Monetary Management*. Prepared for the Commission on Money and Credit.

By FRANK M. TAMAGNA, WARREN L. SMITH, CLARK WARBURTON, MICHAEL D. REAGAN, CHARLES P. KINDLEBERGER, AND ROBERT Z. ALIBER. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. 472. \$6.50.

In 1961 the Commission on Money and Credit published its now familiar recommendations concerning U.S. "monetary, credit, and fiscal policies and the instruments and institutions through which they operate." In forming its views the Commission was aided by a research staff and by a large number of studies, reports, and working papers prepared by various trade associations, by the Federal Reserve and the Treasury, and by individual scholars. In 1962 the Commission began to publish selected reports and studies from among those prepared for it. *Monetary Management*, the first collection of studies by individual scholars to appear (in 1963), contains six contributions. Two of these approach book length; the other four are articles or working papers.

Frank M. Tamagna's 174-page study, "Processes and Instruments of Monetary Policy: A Comparative Analysis," discusses monetary policy formulation and implementation with particular attention to the functions, powers, and influence of foreign central banks. The discussion is arranged by functional topics and draws upon experience in most countries of Western Europe as well as in Argentina, Australia, Japan, New Mexico, and New Zealand. According to the author the study is based on a variety of sources such as laws, statutes and regulations, central bank ordinances, instructions and letters, annual reports, monthly bulletins, speeches, special reports and studies prepared on the occasion of conferences and committee considerations, on

a perusal of general bibliography in the field, and on personal experience with central banking in various countries.

This study is a rich source of information on central bank policies and practice viewed against the backdrop of diverse financial institutions and markets in different countries. Tamagna points out some common themes in this diversity: the dependence of central bank power on the competence, personal authority, and tenure of officials and staff rather than upon legalistic rights, the need for cooperation and coordination between central bank and Treasury operations, and the growing influence of central bankers in national monetary and fiscal affairs in the decade of the 1950's. On the side of diversity are the many variations of practice in open market operations, discount policy, and the use of reserve requirements, as well as variations in responsibility of the central bank for selective credit controls, in the effectiveness of moral suasion, and in central bank regulation of nonbank financial institutions. On this last point Tamagna offers the important observation that any definition of "banking" and "nonbanking" institutions may be highly conditional on particular institutional arrangements and customs and therefore meaningful only for particular countries at a particular time.

Tamagna has not been fully successful in organizing his formidable mass of primary material and giving it focus. His study is almost exclusively a descriptive catalogue of practice. He offers little analysis of the potential application of foreign practice to U.S. problems and makes no recommendation for such application. Thus his study lacks direct relevance to the U.S. scene. As a source for the student of foreign central banking practice, this study can be recommended as a useful survey, but it is too compressed, too descriptive, and possibly inappropriately organized (by topic rather than country) to serve the needs of more scholarly investigation. This shortcoming is reinforced by the complete absence of bibliography and footnote citation.

Warren L. Smith's discussion of "Reserve Requirements in the American Monetary System" is the other major study (141 pp.) contained in the volume. In a clear and forceful style Smith examines a surprising range of topics which turn out to relate to reserve requirements. This range can be indicated by citing some of Smith's conclusions. Traditional reserve requirements against demand deposits should be identical for all banks. On balance the velocity reserve plan is undesirable. Changes in the level of reserve requirements as a countercyclical measure are likely to be awkward and inflexible and thus inferior to open market operations. It might be desirable to take away from the Board of Governors the power to change reserve requirements in normal times. The *level* of reserve requirements has implications with respect to the structure and distribution of government (and private) debt and, in particular, to the proportion of government debt held by commercial banks and the central bank with the money supply held constant. This in turn influences significantly both bank earnings and the net interest cost of the government debt to the Treasury (allowing for the return of interest earnings to the Treasury by the Federal Reserve).

Smith examines a variety of secondary (government security or cash) reserve plans. After noting the problems of transition to such plans he con-

cludes "... one might guess that a requirement amounting to 25 or 30 per cent of demand deposits would produce a substantial stiffening of the impact of monetary policy on bank loans" (p. 271). He analyzes the implications of 100 per cent reserves and doubts that they would improve on the effectiveness of present arrangements for credit control. He is skeptical concerning the need for reserve requirements on time deposits and the liabilities of nonbank financial intermediaries for the purpose of monetary stabilization. He emphasizes that savings banks and savings and loan associations would be deprived of their intermediary function if required to meet reserve requirements identical to those for member-bank demand deposits. He would eliminate reserve requirements against time and savings deposits in commercial banks.

Smith's analysis is supported by a large variety of carefully constructed exercises in the algebra of reserve-deposit multipliers and by illustrative numerical projections of the implications of various reserve plans for such matters as the asset structure of the banking system, bank earnings, and the like. His contribution lies less in the novelty of his material than in the effective manner in which he combines established theory, empirical information, and professional judgment to illuminate policy issues and reach specific and unambiguous recommendations. In the art of applying economic analysis to issues in monetary policy Smith has few peers in the profession today.

Four article-length essays complete the volume. Clark Warburton examines "Nonmember Banks and the Effectiveness of Monetary Policy." He finds the behavior of nonmember banks similar to that of country member banks, which they resemble in size and economic environment. For this reason and because of their relative unimportance in the aggregate of bank assets, Warburton concludes that they do not presently hamper the effectiveness of monetary policy. Should they come to constitute an impediment to monetary policy, Warburton would, in effect, require them to become members.

In "The Internal Structure of the Federal Reserve: A Political Analysis" Michael D. Reagan scrutinizes the organizational structure of the System to assess its implications for such matters as goal formation, interest-group representation in the decision process, and the consistency of its organization with the public (Reagan means "political") nature of the System's functions. Reagan's discussion is fresh and stimulating. He regards the present organization as anachronistic in relation to the public responsibilities that evolution has brought the Board. He favors a more centralized organization, more directly responsible to the President of the United States, and less identified in form (there is no substantive issue) with commercial banking interests.

In one of the remaining papers Charles P. Kindleberger reviews the pros and cons of flexible exchange rates and recommends against a flexible dollar rate on the grounds that "there would be a loss for the world international monetary mechanism." In the other, Robert Z. Aliber discusses "The Adequacy of International Liquidity" and evaluates various proposals to increase it.

Since its appearance in 1961 the *Report* of the Commission on Money and Credit has sometimes been criticized for lack of scholarly originality and

for possible failure by the Commission to rely sufficiently on the professional studies supplied to it by its staff and consultants. On the basis of the observable relationship between the essays in *Monetary Management* and Commission recommendations in relevant areas, the second of these criticisms appears unwarranted. Study of the Commission *Report* reveals substantial correlation between these professional studies and Commission recommendations on such matters as organization and powers of the Federal Reserve System, extension of System membership to nonmember banks, policy toward controls over financial intermediaries, reserve requirements, preservation of the fixed-dollar price of gold, and the development of new forms of international cooperation to meet the growing need for international liquidity. Moreover, the Commission *Report* reflects adequately the spirit of these particular background studies which are more in the nature of policy-oriented applications of accepted professional concepts and available information than they are pioneering studies in the realm of basic social science research. The objective of the Commission was to bring professional competence and experienced judgment to bear on monetary and credit issues and not to sponsor original and basic research. On the evidence of these essays the Commission kept faith with the professional advice which it received.

DONALD R. HODGMAN

*University of Illinois, Urbana*

*Federal Credit Programs. A Series of Research Studies Prepared for the Commission on Money and Credit.* By STEWART JOHNSON AND OTHERS. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. viii, 614. \$6.50.

The 1961 *Report of the Commission on Money and Credit* has generally drawn faint praise in the economic journals, primarily for failing to bring forth any bold new monetary-fiscal concept or institutional proposal. Whatever the merits of this criticism, economists have tended to overlook the pioneering work done by the CMC in the fields of federal credit programs and public regulation of private financial institutions. Here the CMC espoused new approaches for delimiting federal credit operations and for restructuring U.S. financial markets. Its recommendations of principles to guide the federal government's credit activities and to lighten the incubus of governmental regulation of private financial firms so that they would engage in wider interinstitutional competition are of great potential importance.

The volume on *Federal Credit Programs* contains seven research reports that, along with those in a companion volume *Federal Credit Agencies*, helped to shape the CMC philosophy of the role of such programs in the economy. In the present volume Stewart Johnson provides a valuable compilation of facts and statistics on all federal lending and loan insurance programs over the period 1929 through 1958. Warren A. Law presents a study of the aggregate impact of such programs on the entire economy. James W. McKie offers a thoughtful essay on criteria for federal credit assistance, including a treatment of "credit gaps." D. Gale Johnson analyzes the role of federal credit agencies in the agricultural sector. James Gillies performs the same task

for the housing sector. Robert C. Turner and Ross M. Robertson study the sources of funds available to federal lending agencies. J. Fred Weston analyzes the technical components of the programs, including credit standards, interest rates, costs, and nonprice terms.

Each of these studies offers new analysis and fresh insight into its subject. Because a brief review must of necessity be selective, I shall comment only upon the two essays of McKie and Law, which are probably of most general interest to economists because they deal, respectively, with the basic principles justifying federal credit assistance and with the aggregative economic effects of such assistance.

McKie investigated the meaning of "credit gaps," the filling of which has been the primary reason offered for the entry of the federal government into the business of supplying credit. Such gaps exist only in markets which are imperfect by reason of poor organization, ignorance, or ineffective competition (often due to perverse public regulation). They give rise to differences in costs of funds to users greater than can be attributed to differences in risks, administrative costs, or liquidity. True "credit gaps" are investment opportunities whose prospective private benefits would exceed their costs but for the aforesaid barriers. They are to be differentiated from situations in which alleged social benefits exceed private benefits, which are candidates for public subsidies.

Government can properly step in to fill a credit gap when it can realize special economies of scale or can shoulder the burden of surmounting threshold barriers to entry which would endanger the survival of a private enterprise before it could break through to full-scale economies of operation. When government detects a true credit gap—and they are rarer than commonly believed—it can engage in direct lending, lend through an intermediary, insure or guarantee private loans, or institute antitrust or other regulation to stimulate private lending. Direct lending is usually indicated when it is complementary to some existing federal activity; indirect lending when the gap is caused by a threshold barrier; loan insurance when large numbers of similar risks can be economically aggregated; and regulation where competition is ineffective but can be made to work.

McKie's analytical framework is useful in guiding federal action, although more than one of these conditions is present in many credit markets, so that his criteria do not point unambiguously to a single choice. He is premature in branding the Small Business Investment Company—one of the few financial innovations of the postwar era—as unsuccessful in closing the small-business capital financing gap.

Law's careful study of the aggregate impacts of federal credit programs on the economy summarizes extensive recent literature and offers original analysis. It extends and in some respects conceptually improves the pioneering analysis of Saulnier, Halcrow, and Jacoby (hereafter cited as S-H-J).<sup>1</sup> Law was unable to make much progress with such thorny problems in measuring economic impacts as the choice between gross and net flows of federal credit

<sup>1</sup> *Federal Lending and Loan Insurance* (Princeton: Princeton University Press, 1958).

or between direct loans and loan insurance. He defines federal credit simply as the total of direct loans disbursed plus the federally insured or guaranteed parts of private loans. In theory, federal credit makes a real net addition to the GNP only if it generates new income and is not a transfer payment, does not replace private credit, and is derived from funds that would not otherwise have been spent on final products. In practice, it is impossible to determine whether these conditions are met. Law cut the Gordian knot by assuming arbitrarily that *all* federal credit was income-generating and not refinancing of existing debt, the entire net credit flow constituted a net addition to GNP, and funds injected into federal programs by the Treasury were not diverted from potential borrowers so long as there were excess reserves in the banking system. The last assumption is especially heroic; but it is difficult to formulate a better one.

On the key issue of impact of federal housing credit programs upon the postwar supply and price of housing, Law sides with Break who held that the primary effect was an increase in real supply. S-H-J argued to the contrary, that it mainly served to increase housing costs and prices. Clearly, both effects were necessarily present; the issue of their relative importance will never be finally settled.

In considering whether federal credit programs contributed to economic stability, the author rejects the criterion applied by S-H-J, who observed whether the flow of credit increased in years when GNP declined and vice versa (also counting as countercyclical an increase during an initial year of business revival). He used the alternative—and probably superior—criterion of credit increase in years when unemployment exceeded 5 per cent and credit decrease in years when it fell below this level. However, his finding of countercyclical influence in 16 of the 29 years in the period 1929-58 was not materially different from the S-H-J finding of a 15/24 ratio of successes during 1929-53. Both studies confirm the conclusion that any contribution of federal credit programs to economic stability—either at full or less than full employment—has been slight and accidental, and that their postwar influence has been consistently inflationary. The author takes an unwarrantedly dim view of the possibilities of improving the countercyclical effects of credit programs, however, particularly in view of the possibilities of countercyclical shifts in *sources* of funds. Heretofore, there has not been a deliberate “federal credit policy”—only a series of unrelated programs. An agency is needed to coordinate all federal credit programs and to correlate their actions with those of the Federal Reserve and Treasury.

Law found substantial elements of subsidy in the programs, many of which failed to cover costs of funds to the Treasury, losses, administrative costs, and appropriate premiums for risk. (He applied the Krutilla-Eckstein “opportunity cost” criterion of the social cost of federal loans, which was 5-6 per cent per annum during 1955 versus an average market rate paid by the Treasury of 2.85 per cent.) However, some programs did stimulate competition or eliminate divergencies between private and social returns on investment, which justified some subsidization. Federal credit—particularly guarantees—can also be used as a substitute for federal spending. With the benefit of hind-

sight, one can see that a wider application of this form of assistance would have been desirable in the U.S. foreign economic aid programs and in other spheres.

Were these painstaking studies used by the CMC in reaching the recommendations contained in its *Report*? Having served as a member of the Research Advisory Board of the CMC, which mediated between the Commission and its professional researchers, this reviewer would answer in the affirmative. A reading of Chapter 7 of the CMC *Report* clearly reveals a conceptual framework that has much in common with that described above, and the "seven broad guides" put forth by the CMC embody many of the advisers' ideas. In the field of federal credit there was an effective marriage of academic theory and practical experience, although this may not have been true of all aspects of the CMC's work.

*Asset Prices in Economic Analysis.* By SAMUEL B. CHASE, JR. Berkeley and Los Angeles: University of California Press, 1963. Pp. xii, 153. \$5.00.

*Asset Prices in Economic Analysis* is three things, and, hence, must be judged by a triple standard. It is a doctoral dissertation, a treatise on the theory of finance, and a book written in good English. It deserves to be widely read as a fine example of each of these.

It is a brief doctoral dissertation presenting a clear argument in less than 125 pages of text (if allowance is made for the diagrams). It is an exercise in pure logic rather than in computerology. As such, it might well be made compulsory reading for all Ph.D. candidates in economics who have reached the stage where they must choose their dissertation subject and decide on its form.

The theory of finance has attracted the attention of many writers. Despite this widespread interest, one economist's description of one set of ideas might well be applied to the general body of financial analysis. It is "woefully inadequate, unverified, and incapable of bearing the heavy burden that is placed upon it."<sup>1</sup> It is easy to account for this sorry state of our theory. With a few notable exceptions (e.g., Boulding, Goldsmith, and, to a lesser extent, Gurley and Shaw), most writers have centered their attention on relatively limited areas of the economy's asset and liability structure. A synthesis of our views into a conspectus of the role of balance sheets as determinants of economic decisions is now required. Samuel B. Chase, Jr., attempts a conspectus of the structure of assets, and one must agree with him that although his "analysis is highly abstract," it "provides a useful framework for analyzing government financial policies, including central banking, debt management, taxation and budget policy."

He starts from the proposition that "People like to hold assets." However, whereas most analyses move from a discussion of the demand for money to a consideration of the demand for "liquid assets" and on through a range of

<sup>1</sup> Allan H. Meltzer, Testimony to the U.S. House Banking and Currency Committee, as reported in the *New York Times*, Feb. 12, 1964, p. 45.

assets to the demand for and supply of physical assets, Chase proceeds directly to a discussion of the problems associated with physical assets. That is, he starts from a discussion of assets available under conditions of increasing cost in terms of consumption foregone. From this point, he proceeds to a discussion of the factors affecting the price of assets and of the effects of these prices on the demand for and supply of both assets and consumption goods, while always relating these conditions to the demand for money.

Perhaps the outstanding contribution of this work is the discussion which runs through it of the relation between the price, eventually in terms of consumption goods, of a particular asset or group of assets and an individual's wealth. The "wealth effect" of a change in asset prices is a major determinant of the demand for assets. That is, he deals extensively with the knotty problems of unrealized capital gains and losses as determinants of investment and consumption demands.

In general, the analysis is abstract and schematic rather than specific. It deals with the conditions which will determine an individual's distribution of his total wealth among different types of asset, usually in terms of a distribution among real assets, whose prospective prices and earnings are uncertain to different degrees. It is not difficult to transpose these conditions into a description of the factors determining the demands for several types of real asset and different types of financial asset. However, here Chase provides guides which the statistician may use, rather than specific prescriptions.

The abstract quality of the analysis becomes strikingly evident towards the end of the book when the effect of a change in the supply of one type of financial asset—government bonds—on asset and consumption markets is considered. The factors that will determine the relative prices of assets and consumption goods are specified but, in the absence of specific data on the cross elasticities of demand for consumption goods, physical assets, bonds, and cash, an indeterminate conclusion is reached. Yet the discussion of government debt operations serves to outline the fundamental differences between those who believe that "money matters" and those who believe that it is merely a veil. In his final pages, Chase provides a skeletal outline of his approach to fiscal theory and compares it with a simplified Keynesian approach. The essential difference between the two views of the role of a government in the economy is that the Keynesians limit their attention to current flows, ignoring stock effects, while Chase reminds us that any government deficit or surplus permanently changes the community's holdings of bonds and money. These changes alter the community's money wealth and hence shift all future demand curves for assets and consumption.

At this point in the development of our financial theory, a discussion of asset prices at a high level of abstraction is a valuable contribution; but it is not a real conspectus of the role of balance sheets as determinants of economic decisions. It is noticeable that the words "balance sheet" and "liabilities" are missing from the index. In the first place, Chase probably overstates the importance of an analysis limited to assets. Every individual and firm has an inherent asset in the form of borrowing power. If one accepts this view, the issue of liabilities can be treated as the sale of part of this borrowing power. In the abstract, this view is acceptable, yet, if the argument is too

abstract, it may provide misleading guides to policy. A comparative study of "Liabilities in Economic Analysis" might well contribute to our progress towards a proper theory of finance.

In the second place, Chase too readily accepts the view that inherited wealth plus current income provide a homogeneous pool which may be distributed between consumption and investment, with unlimited possibilities to change the composition of asset holdings. Just as "people like to hold assets," they like to keep their assets intact, even in the face of income and price changes which would suggest their dissipation. Further, they like to leave the structure of their assets intact even when shifts in relative prices suggest that they should change the composition of their holdings. Similarly, a sudden rise in incomes will lead quite rationally to splurging which would seem inappropriate on the basis of abstract analysis. These apparently irrational rational forces are among the facts of life which warrant investigation.

In the third place, as Chase states in his preface, "a perfectly competitive pricing system is postulated." He deals only briefly with trading costs and the effects of imperfect markets. In particular, it is, in effect, assumed that borrowing and lending rates of interest are equal. Our world might well be a better place if it were perfectly competitive. Unfortunately, it is not.

These intrusions from "the real world" may well be irrelevant comments. Chase does not pretend to provide a conspectus of financial theory. He has attempted a limited, highly abstract essay. In doing so, he has provided valuable guides which should help to lead us out of our current confused state and towards a satisfactory synthesis of our views.

As a book, this work is a delight to read. In many respects, it moves like a good novel rather than a monograph. At numerous points, the reader is tempted to think "But Chase has forgotten . . .," only to find the point in question discussed on the next page. For those of us who yearn for a return to the literary elegance of the nineteenth century rather than the computer print-outs that pass for economic literature today, many of Chase's sentences are limpid oases. Finally, the University of California Press is to be congratulated for presenting this pleasant essay in a pleasing format.

Washington, D.C.

*From Marshall to Keynes—An Essay on the Monetary Theory of the Cambridge School.* By EPRIME ESHAG. Oxford: Basil Blackwell, 1963. Pp. xxiv, 144. 21s.

A principal aim of this essay on the monetary theory of the Cambridge school is to explain and critically evaluate Alfred Marshall's contribution to monetary theory and policy. In carrying out this task, Mr. Eshag compares Marshall's views with those of the classical economists, with the views of his contemporary neoclassical writers, and with the views of those who followed him at Cambridge. This volume therefore provides both a very broad overview of the development of monetary theory since Ricardo and a more detailed history of monetary theory as it developed in Cambridge from Marshall to Keynes.

The five chapters in this volume take up in turn Marshall's contribution

to monetary theory and policy. The first three chapters are devoted to monetary theory and summarize the analysis of the laws that determine the internal value of money, the external value of money (the theory of exchanges), and the theory of interest. The last two chapters on monetary policy deal with the role of money in the economy including the influence of price changes on trade and production, the analysis of the credit cycle, and the use of alternative monetary instruments to achieve given policy objectives. Eshag's presentation points up the significance of Marshall's views by comparing them with those of his predecessors and contemporaries and by tracing the impact of Marshall's work on the development of monetary theory at Cambridge.

One of the most interesting findings that emerges from Eshag's thorough study of the literature is that, although Marshall contributed many important refinements to classical monetary theory, he did not succeed in constructing a monetary theory capable of explaining fluctuations in income and employment. In large measure Marshall's failure resulted from his primary concern with long-run statics and from his propensity to employ a long-run analysis with an implicit assumption of full employment; he abandoned this framework (emphasizing long-run statics) only when dealing with what he took to be the exceptional case of financial crisis. Thus, even when Marshall turned to short-run problems he analyzed the "credit cycle" but never really attempted to explain the phenomenon of the "trade cycle" or of persistent unemployment. In consequence, his short-run analysis, perhaps too heavily influenced by his preoccupation with the long run, concerned itself with the adverse effects of rapid price changes. Although Marshall does occasionally mention possible changes in output and employment, his analysis of the "credit cycle" focuses primarily on speculative activities induced by changes in the price level; and the greatest evil of these cycles is the financial crisis which develops when credit is contracted at the turning point of a speculative peak and which, in turn, disorganizes trade and brings *temporary* hardship to both entrepreneurs and workers. Marshall did not develop a theory that explains the determinants of aggregate demand and the effect of changes in aggregate demand on employment and output. Eshag's main conclusion is that Marshall's framework was inadequate, his tools ineffective, and his conclusions often misleading. In fairness to Marshall it should be mentioned that a monetary theory based on the analysis of credit cycles was perhaps less inappropriate in the years prior to the 1880's than, say, in the 1930's.

The major contribution of Marshall's successors was to focus monetary theory on short-run problems, to remove the assumption of full employment implicit in the long-run analysis and, most important, to develop an analytical structure that could explain short-run or cyclical fluctuations in employment and output. The monetary problems in Europe during and after World War I resulted from the abandonment of the gold standard, from currency inflations, from the loss of foreign gold reserves (to the United States), and from the loss of productive capacity. And after the Great Depression of the early 1930's, unemployment became the overriding question of policy. Pigou, Lav-

ington, Keynes, Hawtrey, and Robertson, the Cambridge writers considered in this book, made significant contributions in extending the Marshallian analysis and in developing a Cambridge monetary theory in the course of their work on these problems. But the most important innovation was, of course, Keynes' *General Theory* which explicitly considered the possibility of underemployment equilibrium in "normal" (noncrisis) conditions and which laid the basis for the development of a macroeconomic theory in which monetary changes could affect the level of employment and output.

Keynes was primarily interested in developing a theory of employment and a monetary theory of the "trade cycle," and he was not concerned with the analysis of the "credit cycle." Perhaps to emphasize this shift in objectives he felt it necessary to differentiate his product so sharply from Marshall's, in spite of the fact that his method of analysis is Marshallian and many of the ideas he used in the *General Theory* may be found in Marshall. Thus, as Eshag points out in Chapter 4, liquidity preference, the marginal efficiency of capital, and the propensity to consume, three of the important building blocks of the Keynesian savings-investment analysis, have a close affinity to Marshallian propositions. Liquidity preference is related to Marshall's analysis of the "balancing of advantages" in holding money. The marginal efficiency of capital is related to Marshall's analysis of "quasi-rent" and the importance he attached to "confidence" as a determinant of business investment. The propensity to consume and multiplier analysis may be traced to Marshallian views (admittedly the connection here is much weaker) on the "interdependence of firms" and to Marshall's analysis of cumulative processes of expansions and contractions. And even the notion of changes in "effective demand" may be found in rudimentary form in Marshall.

Considering the extent to which the individual building blocks of his analysis were owed to the writings of his predecessors, Keynes appears to be overstating his case against the classical and neoclassical economists when he writes that "the great puzzle of effective demand with which Malthus had wrestled vanished from economic literature." On the other hand, while many of the specific ideas used by Keynes may be traced to Marshall and others, the *General Theory* did constitute a revolutionary departure from received doctrine in developing a theory of aggregate demand, a theory of income determination, a simple aggregative model of the economy, and a general theory of underemployment equilibrium. It is for this reason that Eshag concludes that:

... he [Keynes] was nevertheless, essentially right in claiming that the classical and neo-classical economists, including Marshall, had generally neglected the function of aggregate demand and had built their analysis on the general assumptions of the equality of aggregate demand and supply and of the full employment of labor and equipment in normal (non-crisis) conditions (p. 106).

This is a work of careful scholarship and should be extremely useful to those interested in the history of monetary theory. It contains an excellent exposition of Marshall's monetary theory and traces in detail the evolution

of the post-Marshallian ideas from which Keynes' *General Theory* emerged. It suffers from two minor, though irritating, blemishes: Occasional statements by the author suggest that he is not familiar with the most recent literature of monetary economics (this may be due to the fact that the research for this volume was done some time ago); and the author occasionally allows himself the luxury of stating a personal opinion as if it were an obvious fact. Fortunately, these obiter dicta occur very infrequently and do not detract from the basic merits of the book.

*The Economics of the Credit Union.* By JOHN T. CROTEAU. Detroit: Wayne State University Press, 1963. Pp. xx, 182. \$5.95.

This book is based on studies by the author of various aspects of credit union activity that were commissioned by the National Credit Union Management Conference and presented and discussed at their annual meetings from 1957 through 1962. These studies are the basis for Chapters 2 through 7, which deal with credit union reserves, liquidity, growth, investment yields, and efficiency. The author has added an opening chapter on "The Economic Dimension of Credit Unions" and a final chapter summarizing the conclusions drawn from the studies.

There is much useful and interesting material in this volume, at least from the standpoint of one who is relatively unfamiliar with credit union activity. Chapter 1 raises some interesting theoretical questions. After providing a concise and readable summary of what credit unions do and the legal and institutional constraints under which they operate, John T. Croteau raises the issue of how economic analysis can be applied to the credit union. Here he stresses the cooperative nature of the credit union, which means it is not a profit-maximizing firm, but one "which exists only to further the economic and social aims of its membership . . ." (p. 6). But credit union members include "savers" (those whose borrowings are small relative to their shares) and "borrowers" (those whose share holdings are small relative to their borrowing). The credit union, then, if it is to be an extension of the interests of the membership, may contain the seeds of internal conflict—"savers" want high dividends, which imply high lending rates, and "borrowers" want low borrowing rates, which imply low dividend rates. Croteau points up this problem but does not attempt to resolve it, except to counsel "reasonable compromise (to) arrive at an acceptable course of action" (p. 10). It would seem that economic theory could play some role in analysis of this problem. The credit union (or its directors) may be thought of as elected officials, seeking to choose that combination of dividend rates and interest rates which will maximize the social welfare function of the members. The application of welfare criteria might or might not be fruitful for this problem, but it holds possibilities. As a practical matter Croteau suggests that the conflict is probably won by "savers," since directors and committee members are usually severely

restricted in their borrowing from the credit union. This may lead to restrictions by the directors on the growth of the credit union, since as the credit union grows it becomes more difficult to maintain the ratio of high-yielding personal loans to total assets, and earnings rates fall. This may be accomplished, Croteau suggests, by share limitations or setting aside a high proportion of earnings in the form of reserves and keeping the dividend rate low.

Croteau notes that the "dividend" to members is higher than the stated rate, since most credit unions provide life-savings insurance up to some maximum. This means the credit union has less cash to distribute as a dividend (the insurance is treated as an expense), but it really provides a tax-free dividend in the form of the insurance premiums paid for the member.

In the detailed studies of credit union policies in Chapters 2-7, Croteau does a workmanlike job in developing several arguments with the use of data drawn from 100-300 large credit unions. He suggests in Chapter 2 that approximately three-fourths of the annual addition to reserves for bad loans of these credit unions is a capital reserve since it does not reflect loss experience, and that this may be a way of obtaining interest-free capital and hiding it from members. He argues that legal bad-loan reserve requirements of credit unions provide ample protection against bad losses, and that any excess should be used to increase dividends. In discussing credit union liquidity he develops the argument that the rapid recent growth of credit unions has obscured the cyclical and seasonal liquidity problem, and that should it slow down, more attention will have to be given to individual credit union liquidity. The chapter on "Credit Union Growth" suggests the trend in the growth pattern of credit unions is following a Gompertz curve, with a declining rate of growth, which, however, seems a bit daring as a projection since it is based on annual data for a limited period (1952-57).

Croteau then looks at the growth and balance-sheet characteristics of 175 large credit unions classified by type of credit union, i.e., as to the type of "common bond" (of employment or residence). He finds that the growth of central credit unions was much higher over the period (1954-58) considered than that of other types. Service types of credit unions also had rates of growth well above the average, while credit unions in the "manufacturing and processing" category had rates of growth considerably below the average. The effect of the business cycle is evident in year-to-year growth of certain types of credit unions; e.g., credit unions in steel and auto industries show absolute declines or very small growth in the recession year 1958.

The chapter on "Financial Efficiency in Large Credit Unions" deserves mention. He uses data for large credit unions to show (1) that there are apparently economies of scale in operating expenses among credit unions; (2) dividend payments as a percentage of net earnings tend to rise with the size of the credit union; and (3) net income from operations per \$1000 of assets *falls* as size increases. The third result stems from the fact that the expense economies of large size are evidently more than offset by a lower ratio of personal loans to earning assets; larger credit unions apparently have had diffi-

culty in placing a large enough proportion of their assets in high-yielding personal loans.

The Croteau book can be read with profit by anyone interested in the problems and characteristics of the credit union.

DAVID J. OTT

*Southern Methodist University*

*La banca central en América Latina.* By FRANK TAMAGNA. Mexico City: Centro de Estudios Monetarios Latinoamericanos, 1963. Pp. 603. \$5.00.

This long-awaited work is a curious performance. The position of its author would seem to assure a normal product of U.S. scholarship, with the minor foible that its first publication was in Spanish under the aegis of an organization of Latin American central banks. Instead, the reader finds himself going through almost 400 pages of description and analysis without a single footnote to identify anything, and ten voluminous tables without any indication of the source of their data. No bibliography is to be found in the book, and no index is provided. (No index in the U.S. sense, that is; there is an "Índice general," but that is just a table of contents.) It is apparent that this volume has little in common with what the author would have published in, say, an American university press. The nature and extent of the difference must be sought in the book's history.

The idea of publishing a general study of Latin American central banking originated with the founding of the Center of Latin American Monetary Studies (CEMLA) some ten years ago. Financial support was obtained from the Agency for International Development, and Professor Frank Tamagna of American University was chosen to make the study. He began work in 1958, utilizing the facilities of CEMLA and making personal visits to the countries involved. A draft of the preliminary study was then circulated to the various central banks and was also gone over in detail by a distinguished committee composed of Ignacio Copote Lizarralde, Ernesto Fernández Hurtado, George Garvy, Manuel Noriega Morales, Louis Rasminsky, Javier Márquez, and Alberto Ferrari. The corrections, suggestions, and clarifications put forward by the banks and the special committee were then incorporated in the final draft, with the active participation of the CEMLA staff. This way of putting the book together may account for its resemblance in format to the *Report of the Commission on Money and Credit*, though even that report contained a few footnotes.

The committee approach involves certain difficulties. To take just one example, this is what is said about the imposition of limits on the growth of finance companies in Mexico:

Recently the uneasiness about excessive liquidity in the market, in consequence of the attraction exerted for short-term funds by financial institutions other than banks, led the Banco de México to meet the problem in another way, limiting monthly expansion of short-term debt by way of guarantees extended by finance companies and banks on their own bonds and mortgage certificates in order to transfer the resources and operations to a medium-term market (p. 148).

As it stands, the paragraph is, of course, meaningless. Apparently the original thought was to describe the growth limit of 1 per cent a month which the Banco de México imposed in 1960 on finance companies' term deposits. Then someone wanted to add a note about banks (which are not subject to that growth limit). The references to bonds and mortgage certificates seem to be the remnants of a longer passage discussing the desire of the central bank to stimulate the development of a capital market. The committee approach has its hazards.

The book is organized into ten chapters, each followed by a long table. (The last one goes on for 51 pages.) After a general introduction and an historical sketch, the reader finds a discussion of the evolution of monetary instruments, the formulation of monetary policy, discounts and advances, security transactions, regulation of legal reserves, direct controls, the development function of central banks, and the role of central banks in maintaining economic stability. Each chapter and its accompanying table are filled with details of the activities of each central bank. These data were distilled, in the first instance, from the primary sources available: banking legislation, regulations, annual reports, bulletins, circulars, and announcements of the central banks. The task was arduous; the material is characterized by spottiness, incompleteness, irregularity of appearance, and occasional confusion. Great credit must be given for the completion of this task. But it is difficult to see why, once it was done, the result was not documented. The economist interested in Latin American banking will get much from the book as it stands; he would have been able to get a good deal more if the path of research had been blazed by authenticating footnotes and bibliographic references. The materials digested in the present study were surely no more diffuse and recalcitrant than those employed by Sir John Clapham in his history of the Bank of England. His careful and luminous documentation might have been taken as a model for the present work.

In the case of the tables, a curious anomaly appears. Although the tables are voluminous, taking up a total of 224 pages, they ought to be much more so to accomplish their purpose. At present they serve as a kind of reader's guide to the material contained in each chapter. The data set forth are not quite self-explanatory; to be understood they must be fleshed out by a careful reading of the text of each chapter. In the text, however, the supplementary facts are presented in a catalogue fashion better suited to exposition in a table. Indeed, a step in the obvious direction has already been taken—in the listing of changes in legal reserves by the central banks of Mexico and Argentina. The sketchy information contained in Table VII is amplified by special tables inserted in the text. The indicated solution would appear to be the construction of much more detailed tables, with a corresponding reduction of the purely descriptive portions of the text.

A great many figures are cited in the text, on an *ex cathedra* basis, but no statistical tables are included. It may be said that, given the availability of *International Financial Statistics* of the International Monetary Fund, no such inclusion is necessary. That consideration would be more persuasive if

any cross-referencing to published statistical materials appeared in the text. Without it, the exposition is deprived of much clarity.

The monetary policy of Latin American central banks presents several special features. Economic development is, of course, emphasized at every turn. In addition, a great deal of attention is given to the differences between goods and services. The use of funds to produce services is labeled "unproductive"; to produce goods, "productive." This distinction goes back to one of Adam Smith's more fatuous concepts, one which is still causing a good deal of mischief in the Soviet Union. This peculiarity is mentioned in the present work but not discussed. The general concern with economic development is, however, given a whole chapter, with particular attention to the network of relationships between central banks and the many special development organizations. Other chapters spell out the efforts of the authorities to develop a capital market and their endless battle to maintain a measure of economic stability.

None of the cavils made should obscure the substantial merits of the book. It assembles and presents in coherent form a large amount of detailed information about the organization and operation of Latin American central banks. Given the mutability of these banks, the information is necessarily obsolescent as soon as it appears; so the sponsoring institution promises that a new edition will appear periodically. It is to be hoped that the next edition will not only bring the facts up to date but will supply the additional material which specialists will be hoping to see.

*Federal Reserve Policy Reappraised, 1951-1959.* By DANIEL S. AHEARN.  
New York and London: Columbia University Press, 1963. Pp. xii, 376.  
\$10.00.

This is not a good or useful book for a number of reasons. First, the level of the analysis is low. Much of the book is given over to judicious assessment of plausible and counterplausible arguments. The author picks and chooses according to his taste. Second, it reveals, for all to see, the lack of systematic analysis that often characterizes discussions of monetary policy. So many views are represented and so many economists are quoted that one must conclude that the problem is quite general, though perhaps not universal. Third, relatively strong conclusions follow from extremely weak foundations. The author makes no effort to draw monetary policy conclusions from validated monetary theory. Indeed, monetary or economic theory have no important role in the discussion.

Daniel Ahearn's stated purpose is to investigate "whether the views of monetary policy held by the Federal Reserve, and the action taken . . . , significantly impaired the monetary authorities' ability to influence the money supply, interest rates, the availability of credit, and financial institutions and markets generally." In a short opening section, the "Roosa doctrine" is contrasted to the Board's orthodox and traditional approach. These are presented as rival conceptions of the monetary process. The former is "imaginative"

though a bit "overoptimistic"; in contrast, the Board is unimaginative and fearful of the consequences of interfering in the money market.

The meaning of the difference between Washington and New York, as seen by Ahearn, becomes clearer in the second section, roughly half of the book. This section is mainly an intermittent polemic against "bills only." The author discusses open-market operations, variations in reserve requirements, use of the discount rate, and the failure to use selective controls. In the author's view, three main defects in policy are of particular importance: (1) adherence to "bills only," (2) relatively little use of fiat changes in reserve requirements, and (3) failure to use selective controls.

Adherence to "bills only" is said to have made monetary policy less effective. I never found a clear definition of effectiveness. At times it seems to refer to the relation of policy action to money supply, interest rates, "liquidity," etc. At other times, effectiveness has something to do with the relation of money, interest rates, or liquidity to the pace of economic activity. Apparently, it is all very vague. But it doesn't matter much. Short-term rates are not closely related to long-term rates (pp. 103 ff.), and long-term rates are more "important" (p. 99), so the Federal Reserve could not have done much to affect investment or the financial intermediaries by operating in bills. The author sometimes talks as if there is no relation between short- and long-term yields on governments. "Leaving the long-term markets 'on their own' meant that movements in Treasury bond yields largely reflected movements in yields of private securities such as corporate bonds. When private demand for credit rose, pushing up corporate bond yields, Treasury bond yields were dragged up too by a sort of arbitrage process" (p. 332).

But arbitrage between short- and long-term markets does not seem to occur. Ahearn's discussion proceeds without any mention of an hypothesis concerning the term structure of interest rates. When the two markets are linked (pp. 108-9), it is through "liquidity." "Excess liquidity" is created by saturating the short-term market with "funds" that later "seep into all other sectors of the market." But the excess liquidity has to be absorbed, and this takes time. The result is an impairment of the ability of the Federal Reserve to restrict credit later and to prevent a gold outflow.

Ahearn's treatment of discounting has equally serious shortcomings. He considers a number of alternatives to the present arrangements and concludes that discount rates should be loosely tied to the Treasury bill rate. His criticism of proposals by Tobin and Friedman, in particular, makes no mention of the Federal funds market or of cost and yields on particular methods of reserve adjustments. At times, he accepts the "reluctance" view of bank borrowing (p. 342); at other places (p. 133), he argues that the removal of the Federal Reserve's administrative restrictions would lead to "overborrowing" and the "potential for inflationary enlargement of the reserve base would be enormous."

The discussion of selective controls leads to the conclusion that the Federal Reserve should have standby authority. The argument that monetary controls should interfere little with private decisions is dismissed quickly. Central banking is a process of interference with private decisions. Besides,

"consumer credit is now insensitive to general credit controls and mortgage credit could be . . ." (p. 195). At several places, Ahearn insists that such controls are a supplement, not a substitute for general monetary controls. But his evaluation of their use proceeds as if there were no other policies. For example, he uncritically accepts Saulnier's judgment that by 1949 Regulation W had a dampening effect on the rate of purchase of consumer durables. No mention is made of the consistently deflationary monetary policy pursued by the Federal Reserve during that recession.

The most fascinating assertion in the book is that the Federal Reserve placed "almost exclusive emphasis in 1951-1959 on the money supply as the means through which monetary policy should work" (p. 261). Unless one is as badly confused about the difference between money and bank earning assets (credit) as the Federal Reserve, this is a difficult assertion to support. But it is a major conclusion of the study, since the author would like to see greater attention paid to interest rates, and other variables.

How does he explain the pro-cyclical behavior of the money supply, if the Federal Reserve concentrated attention on controlling money? Part of his answer is that critics have ignored demands for "credit" which, he claims, generate cyclical behavior in the supply of money. Besides, important parts of the money supply behaved countercyclically. The use of his policies would have speeded the reaction to policy, in the author's view.

It is customary to close by recommending the book to someone. In this case it is difficult. The price is high, and the quality is low. But if Ahearn is right and consumers are insensitive to interest rates, perhaps they will turn out to be insensitive to price and quality also.

*Money and Banking: Analysis and Policy.* By CHARLES R. WHITTLESEY, ARTHUR M. FREEDMAN, AND EDWARD S. HERMAN. New York: Macmillan Company; London: Collier-Macmillan, 1963. Pp. xxii, 617. \$8.50.

This new version of Whittlesey's *Principles and Practices of Money and Banking*, most recently published in 1954, parallels other well-regarded elementary texts in terms of length, topics, depth, and organization. Its seven parts range from an introductory discussion of institutional aspects of money and credit, commercial and central banking through analysis of simple classical and Keynesian models, to an examination of financial policy and international finance. There are many charts and tables and a highly selective reference list appended to each of the 30 chapters. Despite a few shortcomings, on the whole the book is well worth careful consideration for a beginning course in money and banking.

An excellent description of credit instruments, including an easy-to-follow arithmetic of price-yield relationships, introduces the standard discussion of banking. The authors distinguish between primary deposits which arise from increases in cash assets of the banking system and derivative deposits which result from individual banks acquiring earning assets for cash.

They explain how deposit balances function as a means of payment—shifting from bank to bank as payments are made. The real bills doctrine—labeled “traditional”—is disposed of with such dispatch that uninformed readers might conclude the doctrine has only historical importance.

The authors define the banking system's potential lending power in the manner of *The Wall Street Journal* as the difference between excess and borrowed reserves. They do not develop this theme analytically, though they return to it in their historical survey of stabilization policies. Instead they pursue the standard analysis of deposit determination as a function of cash reserves, required reserve ratios, and cash flows. This analysis is weakened because the authors fail to focus on the bank demand for cash assets as it affects deposits. The tools for this analysis were available in the very satisfactory discussion of bank portfolio management, the money market, and flow of funds. An appraisal of the role of the reserve period in deposit determination also might have helped the analysis. Member banks have reserve periods of one week if they are reserve city banks and two weeks otherwise (not half months as the authors assert). Reserve requirements need not be satisfied continuously but only on an average basis over a reserve period. Because banks subject to such rules are able to adjust over the reserve period to any gains or losses in reserves, average excess reserves can be kept low and relatively invariant from one reserve period to another—a matter of considerable importance for monetary control.

The analysis of the change in deposits associated with a change in reserves when there is a cash flow is incorrect. This error is common to most current money and banking textbooks. Let  $D$ =deposits;  $R$ =cash reserves;  $r$ =required reserve ratio;  $C$ =currency outside banks; and  $c=C/D$ . No excess reserves are held. The cash flow accompanying deposit expansion is  $c\Delta D$ , and the associated increase in required reserves is  $r\Delta D$ . The authors argue that  $\Delta R=r\Delta D+c\Delta D$  and thus:

$$\Delta D = \frac{\Delta R}{c + r}.$$

This is wrong. If  $R$  really refers to cash reserves, and these are assumed given exogenously, the change in required reserves of  $r\Delta D$  must equal the increase in total reserves,  $\Delta R$ . Hence:

$$\Delta D = \frac{\Delta R}{r} \quad \text{and} \quad \Delta C = \frac{c\Delta R}{r}.$$

The authors' answer is correct only if  $R$  refers not to cash reserves of banks, but to high-powered money—the sum of cash reserves and currency held by the public.

Monetary theory is introduced so as to give the impression that the quantity theory is useful in explaining price levels while Keynesian analysis is designed to explain employment and output. No such theoretical dichotomy need exist. The text has a long section of national income accounting and elementary principles of national income determination, and

short but good nonmathematical discussions of the term structure of interest rates and the interaction of the multiplier and the accelerator. It gives only perfunctory treatment to the vital question of lags in the effect of stabilization policies. It puts little emphasis on expectations in interest-rate determination. Such an omission permits the authors to conclude that money-supply increases would unequivocally reduce market rates of interest. This conclusion is by no means true if one takes account of expected inflation. Such expectations explain why countries with rapidly increasing money stocks and price levels also tend to have relatively high nominal interest rates.

The authors review fiscal and monetary as well as discretionary and automatic policy mixtures; surprisingly they support discretionary general fiscal and monetary policies but hold countercyclical debt-management policy to be ineffectual. They write extensively about liquidity and demonstrate the plurality of meanings associated with that term. They treat inflation, market structure in banking, and the role of banks in effecting international payments briefly but effectively. The book largely satisfies its claim of wedding analysis and policy, although it omits, perhaps justifiably, several major policy arguments of recent years. After all, why should beginning students be expected to grapple with questions the professionals seldom answer alike? Then again, why shouldn't they?

*Evolución de las instituciones financieras en México.* By O. ERNEST MOORE. Mexico City: Centro de Estudios Monetarios Latinoamericanos, 1963. Pp. 413. \$4.00.

*Las sociedades financieras privadas en México.* By ANTONIO CAMPOS ANDA-PIA. Mexico City: Centro de Estudios Monetarios Latinoamericanos, 1963. Pp. 237. \$2.00.

These two useful but unsatisfactory books are symbiotic in more ways than one. Both were published at about the same time in the same series ("Estudios") by the Center of Latin American Monetary Studies (CEMLA); both treat of Mexican financial institutions; and one uses the other as a source. Taken together, they provide the nonspecialist his first full-length portrait of the machinery of Mexican finance.

Mexico's central bank, the Banco de México, with 22.2 per cent of the financial resources of the banking system, supervises the private banks (45 per cent) and the government banks (32.8 per cent). In addition to having the bulk of the financial power situated in the public sector, the Banco de México has substantial police powers which it does not hesitate to use. Its task is made difficult, however, by the persistent fiscal deficits, which have usually been monetized, and by the traditional free exchange of the peso, which lets capital flee abroad at the least alarm.

The government banks exist in great variety:

Banco Nacional de Crédito Agrícola (Farming)  
Banco Nacional de Crédito Ejidal (Communal Farming)  
Banco Nacional de Comercio Exterior (Foreign Trade)  
Financiera Nacional Azucarera (Sugar)  
Nacional Financiera (Infrastructure)  
Banco Nacional Hipotecario Urbano y de Obras Públicas (Public Works)  
Banco Nacional de Fomento Cooperativo (Cooperatives)  
Banco de Pequeño Comercio del Distrito Federal (Small Business)  
Banco Nacional del Ejército y la Armada (Army and Navy)  
Banco Nacional Cinematográfico (Motion Pictures)  
Banco Nacional de Transportes (Transport)

as well as a quantity of special funds, commissions, and facilities. The interesting question of why the Mexican government thought it best to set up all these assorted banks instead of just one is not quite answered by O. Ernest Moore. He does mention that the authorities studied the matter in the 1920's and decided to adopt the European approach, but that is hardly a penetrating answer. Similar superficiality mars his account of the growth and development of each bank. As a handbook containing most of the more important data from the official reports of the Banco de México, Nacional Financiera, etc., the compendium is most useful. Its weakness lies in the fact that little more than official handouts can be found. In consequence, the data for one bank are presented quite differently from those of the next. Some of the sources and uses tables balance; some do not. Occasionally two different sources and uses tables are presented for the same bank and year, neither of which satisfies the requirements for a proper statement. Some of the official reports reproduced uncritically are misleading, as when government subsidies in the form of stock purchases are described as "internally generated funds" ("fondos propios"). And the tables of profits displayed for, say, the Banco Nacional de Comercio Exterior vanish without a mention when it comes to a perennially unprofitable bank like the Banco Nacional de Crédito Ejidal. Surely, to an economist, the losses of the one are just as interesting as the profits of the other. What needs to be done is to sift the data, develop the missing bits and pieces, and then present the result in a uniform and coherent form.

The private banking sector is made up of commercial banks, savings banks, mortgage banks, trust companies, finance companies, and home loan banks. Ever since 1950 the commercial banks have been losing ground to the finance companies. Of the private banking sector's resources, the commercial banks held only 44.4 per cent in 1960, down from 62.8 per cent in 1950, while the finance companies grew from 12.7 per cent to 30.3 per cent in the same period. A good part of the change represents reaction to increasingly severe government control. When the Banco de México was founded in 1925, the required reserves were only 10 per cent and applied only to commercial

banks. Now the required reserves are 100 per cent on some deposits (increased holdings of foreign currency) and 75 per cent on most. Part of the required reserves must be deposited with the Banco de México, part invested in government bonds, and the rest dedicated to prescribed loans and investments. Antonio Campos Andapia is quite laudatory about this process of imposing "minimum coefficients of liquidity" on the banks. As no ready market for Mexican government bonds exists, the fact that they constitute over 13 per cent of commercial bank assets can hardly be said to increase their liquidity.

Mexican banks and finance companies are closely linked; so the mounting required reserves for commercial banks stimulated a flow of funds to the finance companies—by dint of suasion, high interest rates, and the maintenance of complete liquidity. The growth of the finance companies was so rapid that in 1958 the Banco de México imposed reserve requirements on them similar to those of the commercial banks, thus "extending to them all of the advantages developed in the management of legal reserves," and ending their "disloyal competition" with other financial institutions. This concept is developed in a curious paragraph by Campos Andapia which is, in addition, quoted with apparent approval by Moore:

The influence of the private finance companies in raising the rate of interest is attributable to the use to which they have put the resources gathered. They have failed basically to comply with the condition specified in the theory of financial intermediaries to the effect that, in order to exercise a beneficial effect on the economy, they ought to channel their funds toward financing investments. They have perpetrated two principal misallocations of their resources, which have permitted them to obtain an inflated income and, in turn, pay higher rates of return than their competitors. The misallocations involved . . . are as follows: (1) the great quantity of financing devoted to distributive and speculative activities, and (2) the major financing dedicated to investment in their own companies, in which they obtain the going rate of profit, which, by yielding them an inflated income, allows them to overestimate the market rate of interest and pay a higher rate for the savings entrusted to them.

This paragraph epitomizes the attitude of the authorities toward the financial activities of the private sector. Finally, when even the imposition of high reserve requirements failed to halt the growth of the finance companies, from less than one billion pesos in 1950 to more than nine billion in 1960, the government imposed a growth limit on them. The limit varies with the size of the company, but in the main comes to 1 per cent a month in term deposits. Bond emissions are controlled separately.

These two books are useful and provide a quantity of information in convenient form. They are not noticeably analytical; some of the facts set forth are contradictory; major gaps exist in the data; and some of the interpretations offered, especially by Campos Andapia, are ingenuous. In the case of Moore's book, perhaps the right phrase would be "premature publication." With another two-years' work, the book might have been first-rate. As for

Campos Andapia, in all probability no amount of extra time would have made any difference. His effort is obvious and commendable, but his grasp of money and banking is so tenuous as to vitiate the result. The definitive work on Mexican financial institutions has not yet been written.

*New York University*

*Report of the Committee on Inquiry on Decimal Currency.* Presented to Parliament by the Chancellor of the Exchequer by command of Her Majesty, September 1963. (Cmnd. 2145). London: H. M. Stationery Office, 1963. Pp. 253.

As early as 1853, a Select Committee of the House of Commons recommended decimalization of the British currency. Although this recommendation was subsequently reversed in the late nineteenth-century halcyon days, the proposal has the dubious if unique distinction of being the only reform longer delayed than civil rights in the United States.

The Halsbury report, which again recommends decimalization, will presumably soon be discussed by the public and Parliament, where the Chancellor of the Exchequer in 1961 took the position that the Halsbury Committee "is not being asked to consider the question of 'whether,' but the question of 'how' to decimalize" (p. 2).

Almost all the Commonwealth nations—India, Pakistan, Australia, New Zealand, and others—have already decimalized, or decided to do so. South Africa has as well, and Canada has a dollar-cent decimal currency.

To replace the coinage and the machinery of counting and computing will be costly—the Report estimates £109-£128 million. If despite the recommendation the cost is deemed prohibitive, decimalization could be delayed, and Mr. Selwyn Lloyd, Chancellor of the Exchequer at the time the Halsbury group was appointed, provided this loophole in his remarks to Parliament.

The Committee lists eight criteria which they deem desirable in a decimal system: it should be consistent, simple, flexible, lasting, should not affect the international standing of sterling, should not present people undue difficulties in the transition, should not result in avoidable price increases, and should not result in unduly high machine costs.

To decimalize the current British currency, with its assortment of multiples of 12's and 20's,<sup>1</sup> the Committee argues it can move, basically, in one of three ways, up or down from the three basic British currency units, the pence, the shilling, and the pound. In large measure, any choice is arbitrary. "There is no perfect answer."

Thus if one opts to move up from the pence, by creating a unit equal to 100d., that unit would be worth 8s. 4d. The Committee rejected this type of decimalization.

<sup>1</sup>For readers who have forgotten the basis of British currency, there are 12 pence (d.) per shilling (s.) and 20 shillings per pound (£). Since the pound is now valued at \$2.80, a shilling is valued at 14¢, and a pence at 1.1666¢. The key problem in decimalization is to replace the base of 12 (pence to shilling) with a base unit of 10, similar to the shifting from 12 inches to a metric unit in the United States. There are, of course, broader ramifications of this conversion, some of which this review explores.

From the shilling, the Committee considered a basic unit equal to 10s., with each 'cent' being worth 1.2d. The minority of two of the Committee recommends the adoption of this unit.

However, the majority (of four) recommends the third alternative: using the present pound, each of whose one-hundredth part subunits would be worth 2.4d. Now since 2.4d. is a very large minimum unit at current prices, the majority realizes it will have to add, for the convenience of the whole system, a smaller minimum unit, the  $\frac{1}{2}\phi$ , worth 1.2d.

The Committee is aware that adding this fraction—or technically adding this mil digit to a decimal system, since the  $\frac{1}{2}\phi$  would be worth £.005—adds a "vulgar fraction," whose "introduction undoubtedly complicates a decimal system and therefore probably makes mental calculation and change giving slower and more liable to error." Further, "machines needed to record vulgar fractions, . . . would have to be non-standard. If required to record the fraction decimally, i.e. as .005, machines would have to be of higher capacity and thus more expensive. Manufacturers of business machines and of electronic data processing equipment are strongly opposed to the use of vulgar fractions."<sup>2</sup>

Put differently, the excessively high minimum coin (2.4d.) means that the pound is too large a unit to start with. The Committee had been concerned with long-term inflation of prices in its thinking; it cited something like a 14-fold rise since the fifteenth century—and the criterion that "the system should last" clearly eschews a minimum unit which will fall into disuse as prices rise. The Italian lire, e.g., was once divided into 100 cents, but now even the smaller lire units are not usable. Nevertheless, the £- $\phi$ - $\frac{1}{2}$  system would seem to err on the high side, for the present at least.

In view of these pre-announced difficulties, the reader may be at something of a loss to understand the selection of this seemingly most cumbersome and least-true decimal system of the three. It must be inferred, but seems quite clear, that the overriding consideration behind the majority's selection of this £-cent- $\frac{1}{2}$  system, despite its drawbacks, is the desire to retain the pound as the basic unit of currency. This desire not only reflects the importance, in the Committee's mind, of the pound as a unit of international reserve, with all that implies, but also raises the issue of "associability," with which the Committee is concerned.

Stated simply, "associability" is assumed to be good because a new currency "should" retain some landmarks familiar in the old currency. In each of the three methods of decimalization outlined above, there is some landmark—the pence, the 10-bob note, and the pound. But quite clearly the landmarks virtually end there, for except for a random coin here and there, most of the units would need to be quite new. That associability is taken seriously is doubly surprising in view of the findings of the Applied Psychology Research Unit at Cambridge, which worked with the Committee on this problem. "One surprising result of these experiments was, indeed, the better performance which British subjects achieved in mental arithmetic using the U.S.

<sup>2</sup> P. 12. Also see Chapter 8, paragraphs 287 to 293.

dollar and cent system than the £ s d system they had been using all their lives."<sup>3</sup>

The Committee is also concerned with two cost factors. The cost of new coin and computer machinery has been noted. It comprises the bulk of the estimated cost of decimalization. Second, the matter of price adjustments receives great attention. Clearly, fine adjustments of price—the current  $\frac{1}{2}$ d.—would be wiped out, particularly if the minimum unit of the new coinage were too large. In the two plans recommended, the 10s. of the minority and the £-¢- $\frac{1}{2}$  of the majority, the minimum unit is 1.2d.; in the majority report this is only attained by adding the  $\frac{1}{2}$ ¢ unit—worth 1.2d.—and thus destroying the decimal system.

So much for the Committee's Report. That it is thorough and scholarly will surprise no one who is familiar with the Committee members. That it neither makes easy nor interesting reading probably flows from the subject matter. That its horizons are limited may well flow from the frame of reference within which the Committee was asked to work.

Freed from any restrictive frame of reference, save decimalization itself, it seems to me a better plan could be put forward.

Briefly stated, this is that decimalization be based on a new British unit currently worth 7s. 2d. A moment's reflection will reveal this to be equal to a U.S. dollar, while the unit could be called anything, e.g., an "Elizabeth," the following proposal may for the present be called the "British dollar" plan. The proposed British dollar would be divided into 100 cents whose multiples would doubtless in time by colloquial usage be called something other than dimes and quarters.

There are four ideas behind this proposal. The first is technical. This system meets better than any other the criteria set forth in the Report and avoids most of the pitfalls of the plans currently recommended. The units are small and viable. They provide a consistent and unbroken decimal system, unlike the majority proposal £-¢- $\frac{1}{2}$ . The units are not insularly English but increasingly universal in the English-speaking world. As the Cambridge study noted, Britons can handle the dollar-cent system better than their own. Machines for this coinage are readily available from North America, and in time North America, Australia, and other areas could well import the products of the British coin and related machine industry, which would have export advantages.

Perhaps the most important technical consideration bears on the problem of price increases in the transition, and the related problem of wage rates, etc., to which the Report gives a full hearing. The trouble with both the majority £-¢- $\frac{1}{2}$  plan and the minority 10s-¢ plan, apart from the "vulgar fraction" break in decimalization in the former, and insularity of the latter, is that the minimum unit, the cent, equal to 1.2d. in both plans, is too big. Every price or wage now measured in  $\frac{1}{2}$ d. would be rounded up, it is feared, nearly threefold. (Obviously eventually competition and not currency must be relied upon to hone price adjustments.) In the transition and beyond, however, the ¢ unit in the "British dollar plan" here proposed is .86d., much closer

<sup>3</sup> P. 13. Also see Appendix 8, paragraphs 5 to 15.

to the current  $\frac{1}{2}$ d. than any other minimum unit proposed, and a unit, given the arguments in the report, that seems just about right as a starting coin.

In general, I tend to give little credence to the "associability" argument. If justification is needed, it is clear to me that no system will provide real associability; all will provide random bits. For example in the proposed £-¢- $\frac{1}{2}$  system, the shilling can remain, equivalent in stature to the American nickel. In the British-dollar plan, the 2s. 6d. coin (half a crown) could remain, equivalent to 35¢. But neither of these "associated" coins will buy what it once did; like false cognates in a foreign language, these old familiar "landmarks" may well be more misleading than helpful. Coin machinery would still need to be replaced to take into account new price relationships. As the Cambridge study cited implies, a new and rational system would actually be easier to adapt to. This study, and South African experience, suggest that adaptation should be considered a matter of weeks rather than months. "Associability" may well be a misleading criterion, best abandoned.

Second, and perhaps most important from a British viewpoint, the present British pound could be retained as the historic lynchpin of British currency, and of the extensive system of international accounts which center on sterling. The "British dollar" would be linked in value to the pound sterling at its current value, so there is no possibility of the outside world losing confidence because of an apparent change. The arithmetic of the process is simple: £5 would be exactly equal to 14 British dollars. Though the pound would remain unchanged and unchallenged in the background, all daily working transactions could be carried out in the new "British dollar." The pound and the British dollar would, in relation to other currencies, move up and down the exchange (within IMF limits) exactly as the pound now does, a function of confidence and demand. The managers of the two great reserve currencies—the U.S. dollar and the pound—would consider each other's strengths and needs in exactly the same way they now do. They would work together in bilateral arrangements (swaps, etc.) to support each other's reserves against swings of trade or confidence; and similarly in wider groupings—in the Group of Ten and in IMF—mutual understanding and cooperation, which has made such striking progress in the last few years, would continue along present lines.

Third, the adoption of what amounts to a common internal currency would provide for the U.S. and British economies a common measuring rod on movements of costs and prices. Until now the two economies have been insulated from each other at the level of daily working contacts. A common currency makes understanding of each other's cost structure and behind this of production methods possible in ways much easier for lessons to be learned and applied without the intervention of heavy statistical interpretations of experts. Such interpretations may make good reading in the *American Economic Review* or the Oxford Bulletins, but are unintelligible to the factory manager and shop steward who must understand and improve productivity relationships.

Finally there is a political motive to this plan. At this moment in history

the British people could make a change which would be a momentous step forward in Anglo-American cooperation. By adopting in effect a common currency, the great forward step would be accomplished without negotiation, without treaties, and without any loss of financial independence by either the United Kingdom or the United States. Rather than adopt a unique and insular decimal system, the British could, with no more effort (indeed less) bring the reserve currency—sterling—and the British internal currency, the “British dollar” here proposed, into a new and close relationship with the other major reserve currency—the U.S. dollar.

### Public Finance; Fiscal Policy

*Fiscal and Debt Management Policies.* A Series of Research Studies Prepared for the Commission on Money and Credit. By WILLIAM FELLNER, RICHARD A. MUSGRAVE, JAMES TOBIN, JAMES R. SCHLESINGER, PAUL H. COOTNER, IRVING AUERBACH, RALPH K. HUITT, AND JOHN LINDEMAN. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. 539. \$6.50.

This is one of nine volumes presenting eight of the many research studies prepared as background papers for the Commission on Money and Credit. If they are a fair sample, the Commission had some excellent material to work with and fulfilled well what was perhaps its most important function, the stimulation of new thinking and research. It must be regretted that the Commission took over three years to publish these papers, which has diminished the social usefulness of the work. It is astonishing that the papers have stood the passage of time so well.

The book begins with two important papers on tax policy. Professor Fellner presents a carefully qualified argument that our tax system should be re-directed away from income taxation towards sales taxation. He advances three lines of reasoning: first, while extreme beliefs on the disincentive effects of income taxation were debunked by scientific investigation, the evidence does not show the effects to be totally absent, and we may have swung too far the other way in our skepticism. Second, the particular notions of equity which justify progressive income taxation are not the only reasonable notions of equity. Sales taxes with exemptions for necessities could promote another kind of equity, presumably a penalization of high living. Finally, he cites international comparisons on the percentage of the tax burden which various countries collect in the form of direct taxes and finds the United States out of line.

Fellner sees two possible ways in which our tax system could move towards greater reliance on sales taxes. If the greatly rising costs of education continue to be financed at the state and local level, the adjustment would come almost automatically. The federal government would, under reasonable assumptions, have room for tax reduction. State and local governments would be forced to increase their tax rates, which would be largely sales (and property) tax increases. Alternatively, the federal government could begin to shoulder more

of the cost of education—an issue he would resolve on educational grounds—in which event he would seriously consider the institution of a federal sales tax with “appropriate exemptions.”

Fellner's uneasiness about disincentive effects is now shared more widely. I find the argument about achieving equity through sales taxes less persuasive. A sales tax designed to be a major revenue source must include a wide range of commodities, too wide a range to discriminate meaningfully among income classes. Even if food and children's clothing are omitted, the income elasticity of demand for the remaining consumption items cannot exceed unity by much. In this age of mass consumption it is difficult to select categories of goods and services for taxation which are not bought by families in most of the income ranges. Certainly not enough items could be identified to constitute a major tax base. Nor do I believe that a major reduction in income taxes in the United States can be rationalized through international comparisons. While we do levy a somewhat greater fraction of our total taxes on income than the major European countries usually chosen for comparison, this difference is largely due to our higher income levels and the greater scope of the corporate sector, not to higher rate structures.

Fellner writes as if he were a voice in the wilderness. But events have caught up with him surprisingly rapidly. In the three years since he wrote, the tax system has developed exactly as he said: income taxes have fallen under growing suspicion; the federal government has enacted large income tax reductions, and state sales and property taxes have been increased to meet the costs of education. It remains to be seen whether the switch from direct to indirect taxation will, in fact, raise the saving and investment rates.

Richard Musgrave questions whether changes in the composition of the tax system can raise the saving rate. While he ranges authoritatively over the full set of relevant issues, including the proper treatment of capital gains, the integration of the personal and corporate income tax, the effects of the high marginal rates, etc., the heart of his paper is a numerical analysis of the impact of the tax structure on aggregate savings. Using survey data and judgment estimates, he derives the marginal impact of changes in the major taxes on saving. He assumes that 80 per cent of the change in corporation income and estate taxes falls on savings, 31 per cent of individual income taxes, 18 per cent of sales taxes, and 25 per cent of property taxes, making for an average impact of 36 per cent for the entire tax system. Given these figures, Musgrave finds that the impact of the tax system on savings is large, but that plausible changes in the composition of the tax system would not raise savings, except for a switch away from corporation income taxation. Since he finds that tax to be shifted in his more recent work with Krzyzaniak, even that possibility is now ruled out. Thus, the full-employment saving rate can only be raised through a higher budget surplus.

Musgrave's analysis seems to me to overstate the impact of taxes on savings. The figure for the personal income tax, which is the most important, is largely based on very high marginal savings rates on incomes over \$15,000, where two-thirds of the savings impact accrues. This rate is assumed to reach 50 per cent at an income level of \$17,000 a year. There is virtually no in-

formation on the savings behavior of these groups, making the estimate very uncertain. I would judge the long-run marginal saving propensity in these brackets to be substantially less than 50 per cent. Musgrave's estimate can perhaps be explained by his statement later in the paper that these incomes are largely from capital. But this is not really borne out by his figures; even in the \$50,000-\$100,000 bracket more than one-half of all income is payment for personal services.

The remaining papers deal with monetary questions. James Tobin applies a portfolio model to debt management. He defines debt to include all debt of government, including noninterest-bearing currency. He then divides the effects of the debt into two kinds, fiscal effects, which are identified with the multipliers applied to the surpluses and deficits that cause the debt to change, and monetary effects, which result from "the private ownership of claims against central government," and which persist as long as the debt exists.

Since the public debt represents private wealth (as long as individuals do not consider their share of the public debt as an offset), the monetary effect of an increase in the debt is considered expansionary. Tobin uses his portfolio model to work out the implications of this statement in some detail. For example, if the increase in the debt is in the form of short-term securities, individuals will not wish to hold the entire increment of private wealth in this short-term form but will put part of the increment into private equity capital. This switching will reduce the supply price of private equity capital, and encourage investment. Similar analyses are offered for demand debt and long-term debt. Tobin also uses his portfolio model to analyze the impact of changes in the maturity structure of the debt and reaches the conventional conclusion that a lengthening of the debt has a contractionary effect.

While this portfolio-effects analysis is useful and, in the hands of Tobin, yields some significant insights into the repercussions of the existence of the stock of public debt, there is a hazard that it directs attention away from other monetary effects which may be more important. When Tobin analyzes an "increase" in the debt, he makes a static comparison of two situations identical in every respect except the size of the stock of debt. This leaves no room for the process of debt-increase itself, which is usually taken to have a contractionary monetary effect. Tobin must assume that the process of issuing new debt is accompanied by monetary policy actions of ease which exactly offset the initial negative impact on the supply price of capital for private investment.

Tobin also deals with the choice of objectives of debt management and monetary policy. He proposes that the interest cost of the debt to the taxpayers be minimized, given the proper contribution of money and credit policy to stabilization. He does not elevate minimum interest costs to be an objective of high priority, but rather argues that whatever the possible contribution of monetary measures to stabilization may be, it can be achieved in various alternative ways: within the family of money and credit instruments he would favor the use of a set of tools that would keep interest costs to a minimum. For example, the money supply should not be expanded secularly by a reduction of commercial bank requirements, as has been done in recent years,

but by open market purchases. Further, he would ask for sympathetic consideration of reserve requirements for nonbank financial institutions which would force them to hold a certain amount of government debt.

Finally, Tobin endorses the proposal for purchasing power bonds escalated by the consumer price index. He argues that the private investor has a large menu of possible investment media available to him, but that despite this proliferation, he still has to choose between a set of securities having a very low specific risk but not hedged against inflation, and another set of securities which is at least crudely hedged against inflation but has the high specific risks of equity investment. Only the government is in a position to insure against changes in the consumer price index, and Tobin argues that it has an obligation to offer this form of insurance to the public. It is unfortunate that the equity aspect of the purchasing power bond has been so little considered and the proposal has never really received a serious hearing in this country because of the unproved assertions about its effects on the preservation of fiscal discipline and the spreading of mass inflation psychology.

Two papers deal with potential new tools for monetary policy. James Schlesinger analyzes proposals to insulate the market for federal debt. I think it is safe to say that his paper buries the idea for the present. Most of the proposals, such as the supplementary security-reserve scheme which would have required banks to hold government securities as a secondary reserve, were made in the immediate postwar years, when the public debt loomed much larger in the economy and was an apparently insurmountable obstacle to an effective, flexible monetary policy. Schlesinger finds that it would have made excellent sense to finance the war through a scheme that would have frozen the new bank reserves as they were created, and that much later trouble would have been avoided. Banks could have been required to purchase and keep securities as British banks were required to do. But with the war-time opportunity missed, and with the banks holding large quantities of marketable government bonds, it would have taken very drastic proposals to achieve insulation, with the social costs considerable and the gains uncertain.

Since the main goal of insulation was to restore Federal Reserve control over the volume of bank loans, Schlesinger appraises insulation as a form of direct control to serve that end. On that criterion it is feasible, but there are more effective control instruments, such as the velocity plan for reserve requirements, differentiated reserve requirements against different forms of assets, or direct limitations on bank loans.

Irving Auerbach examines the instrument of Treasury cash balances as a means of controlling commercial bank reserves. He concludes that in principle this could be a very powerful device. It can be more selective than open market operations and could affect banks quickly, even those remote from the money market. It might make it possible for the authorities to meet their free-reserve targets more precisely than they do now. The initial impact of monetary policy would no longer occur in the government securities market. And even now the instrument is used to insulate commercial bank reserves from short-run swings in federal receipts and payments.

Nevertheless, Auerbach does not recommend use of the Treasury cash bal-

ances for broad policy. He feels that present instruments suffice to regulate bank reserves. But the main arguments are political and administrative. First, the Treasury might be running monetary policy, though this difficulty could be overcome by delegation of the responsibility to the Federal Reserve System. Second, there is the possibility of abuse. In the late nineteenth century, when Treasury balances were used to run at least a counterseasonal monetary policy, the system left room for favoritism by making funds available to certain private banks without interest cost (the famous "pet banks"). Since use of this instrument would require Treasury balances to be kept in excess of the amounts necessary for the normal financial operations of government, it would increase the interest cost paid by taxpayers to the benefit of the banks holding the excess deposits.

Paul Cootner's paper is of considerable theoretical importance but does not cast much light on the question the Commission posed him: what has been the role of speculation in the government securities market and what should be done about it? He builds an elaborate and suggestive model of bank liquidity behavior that will be of interest to monetary theorists; the model is tested by correlations of differentials between long- and short-term interest rates against the levels of these rates. It turns out that the differentials widen when long-term rates are low, which is consistent with his theory (and many others). Cootner then takes his theory to be verified and concludes that since banks act according to his theory, they serve to stabilize the market. He finds that "the market has been quite good in a stochastic sense," and attributes its wide swings to the pursuit of economic stabilization policies by the authorities.

To anyone who has read the Federal Reserve-Treasury Study account of the speculative collapse of the bond market in the summer of 1958, this is an incredible conclusion. No amount of theorizing is going to be able to discover from a correlation of interest rate differentials against interest rate levels whether or not speculators widened the swings of the government bond market. Cootner makes little use of the materials of the Treasury-Federal Reserve Study, and the mix of theorizing to research is askew here.

Two more papers complete the volume. Ralph K. Huitt, a political scientist, presents a skillful and perceptive analysis of the role of the Congress in the formation of economic policy. Finally, John Lindeman surveys political and administrative arrangements affecting foreign credit operations, emphasizing particularly the role of the National Advisory Council on International Monetary and Financial Problems.

// *The Shifting of the Corporation Income Tax—An Empirical Study of Its Short-Run Effect upon the Rate of Return.* By MARIAN KRZYŻANIAK AND RICHARD A. MUSGRAVE. Baltimore: Johns Hopkins Press, 1963. Pp. viii, 100. \$4.00.

The U.S. corporation income tax occupies a central role in the tax structure of the public sector and takes a major cut of the profits of the corporate

enterprise.<sup>1</sup> The corporate income tax is the federal government's second-largest revenue source. It is expected to yield \$25.8 billion in the coming fiscal year. Despite its obvious importance, the economic effects of the tax remain largely unmeasured. Lewis [8] and Goode [4] have studied its aggregate dynamic characteristics and theoretical impact; Harberger [6] and Lintner and Butters [9] have attempted to measure the impact of the tax on market organization and allocation; Eisner [3] and Hall [5] have studied the interaction between the tax and certain corporate costs.

The history of the corporate income tax is marked by controversies. Economists have been unable to link the tax directly to the benefits from government services received. Nor have they supplied a rationale for taxing consumers and investors indirectly through a profits tax. Indeed, inferences about the economic effects of the tax depend heavily on knowledge of the incidence of the tax between consumers and investors. If investors bear the ultimate burden, the tax may limit investment and growth. If consumers bear the ultimate burden, our corporate product may be at a competitive disadvantage in markets abroad. Enlightened economic policy-making thus requires good evidence on the incidence of the tax.

This is the setting within which Marian Krzyzaniak and Richard Musgrave present their study. They examine corporate response to changing tax rates for the period 1935-59. They undertake the difficult task of disentangling tax-induced behavior from the myriad of exogenous influences on the corporation. Their discussion of corporate responses to tax rate changes in the context of a closed economic system constitutes a major contribution not only to the study of this problem but also to the study of other tax-induced behavior.<sup>2</sup>

The book combines four elements: (1) theoretical derivations of measures of the degree of tax shifting, (2) alternative models of corporate responses to changing levels of tax rates, (3) estimates of those models, and (4) the derived estimates of corporate tax shifting. In Chapter 2 the authors display a variety of indices that measure tax-induced corporate behavior. To replicate various findings that have been published in the literature (Adelman [1], Lerner and Hendriksen [7]), the authors show gross changes in these indices without any adjustment for other changes in the corporate economic environment. Zero tax shifting is implied by gross changes in the index—profit plus interest as a proportion of corporate value-added—between 1922 and 1959. Gross changes in the level of manufacturing rates of return imply shifting in excess of 100 per cent from 1936-39 to 1955-57.

The heart of the study consists of estimating the effect of taxation on the rate of return *ceteris paribus*. The magnitude of the effect is estimated from a relationship that includes other predetermined influences on corporate rates of return. Estimates are based on annual observations from 1935 to 1959,

<sup>1</sup>In 1959, 11.5 per cent of all active corporations paid taxes at marginal rates of 52 or 54 per cent. These corporations received 93 per cent of corporate income. See Internal Revenue Service, *Statistics of Income: 1959-60 Corporation Income Tax Returns*, p. 112.

<sup>2</sup>The shortcomings of some of the past work are discussed in Zellner [10].

excluding 1943-47. Two behavior hypotheses are tested: Model A asserts that the corporation increases its gross rate of return ( $Y_g$ ) over the no-tax rate of return ( $Y'$ ) by some fraction ( $a$ ) of the *tax* in relation to capital, i.e.,

$$Y_g - Y' = a (T/K).$$

Model B asserts that the increase in gross rate of return over no-tax rate of return is some fraction ( $b$ ) of the *tax rate*,

$$Y_g - Y' = b Z.$$

Actually Model A is identical to the assumption that the firm increases its rate of return by a percentage equal to a fraction  $a$  of the tax rate  $Z$ . Both models are estimated in equations where linear combinations of lagged consumption, the lagged ratio of inventory to sales, the present personal tax rate, and present government expenditures represent the no-tax rate of return. The estimates of both models imply shifting by manufacturing corporation significantly in excess of 100 per cent.<sup>3</sup>

A brief excursion into estimation of the tax parameter of Model A for some selected industries discloses that small and large corporations have similar behavior, but there is a range of behavior among industries generally consistent with 100 per cent shifting. Somewhat higher values of the tax parameter are estimated for a group of firms chosen as "price leaders" than for another sample group of "price followers."

A parallel analysis of tax effects on flow of funds is presented with related studies in Chapter 7. Coefficients are estimated for Model A when the dependent variable includes both profit and depreciation as a proportion of equity. The authors recognize that corporation responses to changing acceleration of depreciation will be attributed to the tax coefficient estimated whether rate of return or flow of funds is used as the dependent variable.<sup>4</sup> Because of a general increase in the degree of acceleration over the period 1935-59, actual corporate response to changing tax rates must lie between the values estimated for the tax coefficient in the two equations (1.23 for the equation based on rate of return, 1.46 for the equation based on flow of funds).

The analyses suggest a variety of further work:

1. Interindustry differences in tax responsiveness ought to be examined in relation to capital-output ratios and market structure. Capital-output ratios

<sup>3</sup>  $R^2$  equals .93 for Model B, .98 for Model A (standard version). Goodness of fit is the authors' primary argument for concentrating estimation on Model A.

An instrumental variable technique is used to estimate Model A. However, in nearly all estimates the effective tax rate  $T$  is used as an instrument in spite of the fact that it is an endogenous variable in the system. In the one case where the more appropriate statutory tax rate variable is used as an instrument for Model A, the coefficients are almost identical to those obtained from estimates based on effective tax rates.

The reader will be spared some bewilderment by noting that numerous relationships are derived in Appendix C on the assumption that  $a_4 = 1 + A_4$ . According to footnote 8, page 26, the relationship must be  $a_4 = 1 - A_4$ .

<sup>4</sup> It is not clear why the authors did not use degree of acceleration as an independent explanatory variable, perhaps as a determinant of the parameters  $a$  and  $b$ .

are relevant because of the unresolved question as to how changes in depreciation for tax purposes affect the estimated parameters ( $a$  and  $b$ ). Market structure may account for differences in the ability of a firm to engage in price changes at the time of tax rate changes. If so, a regular relationship between market structure and tax responsiveness should emerge.

2. The short-run dynamics of corporate response to the tax rate might be studied. In the model estimated the tax parameter reflects the degree to which corporations have responded to a level of tax rates. The fact that lagged values of the tax variable contribute insignificantly to the relationship suggests that adjustment is complete within the first year. What happens within that year? The problem could be studied on the basis of available quarterly series with a model that gives estimates of the speed with which corporate business adjusts to new tax environments.

3. A study of tax adjustment in the utility industry, particularly electric utilities, would be most informative. Price regulation entails legally endorsed shifting of taxes to the consumer. Estimates of the tax parameters of Model A for this industry might help to explain why manufacturing industries appear to have responded to changes in taxation in a way that overcompensates for the initial change.

4. The models ought to be estimated on the assumption that businesses respond to changes in tax rates by adjusting the absolute level of profit rather than a rate of return. Such models can be derived from A and B by multiplying each expression by the level of capital stock. Estimates on that basis would be relevant for a variety of reasons. Business may act on the basis of profit position in its pricing behavior; if so, statistical fit could be improved by estimates derived from profit relationships. Estimates based on rate of return may obscure the short-run adjustment as any uncompensated exogenous shock on profits will alter corporate net worth in the following period if corporations maintain constant dividend rates.<sup>5</sup> Thus changes in rate of return may not be a suitable index of corporation adjustment to changes in tax rates in the short run. Finally, it is the absolute profit which appears in most structural models of the United States. It would be instructive to compare the tax response of corporate profits in the Klein-Goldberger and similar models with the response indicated in the authors' formulation.

Despite the fact that the authors make no claim to studying the incidence and growth effects of the corporate income tax, they cannot be forgiven for omitting a chapter on those subjects. Determining the response of corporate enterprise to taxation is of interest primarily because of the far-reaching consequences that response might have for investment, the dynamic and static incidence of our tax structure,<sup>6</sup> and the growth of the economy. A few remarks on the implications of this study for tax policy that appear on page 66 are inadequate and confusing. The authors suggest that the tax is similar to

<sup>5</sup> The existence of some relationship of this kind may explain why residuals from both models fail to pass the Durbin-Watson test for negative serial autocorrelation.

<sup>6</sup> Dynamic incidence refers to the impact of the tax system on changes in income. See Douglas Dosser [2].

a general sales tax on corporate capital and consumer goods. Variation in the profitability and the proportion of value-added originating in corporate rather than noncorporate enterprises in different industries implies that the specific sales tax rate applicable to a given firm would need to vary substantially to replicate the impact of a shifted corporate income tax. The authors indicate that such variations will cause the tax to distort relative price levels. Sufficient relative price movements may be generated by such forward shifting to cause sizable misallocation of resources [6], even in a period as short as the annual period studied by the authors.

In this work Krzyzaniak and Musgrave demonstrate the need to apply well-conceived econometric models for the analysis of tax-induced behavior. Students of business behavior will find this work stimulating and suggestive of further work.

*Public Finance and Budgetary Policy*. By ALAN WILLIAMS. New York: Frederick A. Praeger, 1963. Pp. 283. \$8.50:

Mr. Alan Williams' book grew out of a course given for honors students at the University of Exeter. The work is entirely theoretical, and it is not easy reading. The analysis rests on complicated graphs, many of them three-dimensional.

Part A deals with microeconomic effects of government tax and expenditure policy. Williams begins with the analysis of the effects of lump-sum taxes, income taxes, expenditure taxes, and wealth taxes on work effort, savings, and financial investment. There are two chapters on the effects of business taxes. Using the conventional partial-equilibrium theory of the firm, Williams studies the impact of lump-sum taxes, profit taxes, value-added taxes, gross-revenue taxes, and gross-cost taxes on price and output policy. Chapters 9 and 10, respectively, are devoted to the question of excess burden and the incidence of various expenditure policies.

Part B of the book, entitled "Macroeconomics," begins with a study of the general equilibrium aspects of tax and expenditure policy. The remaining one-seventh of the book is devoted to questions of stability and growth.

The first sections of this work are the most useful and comprehensive. Although much of this material is standard fare, there are a number of extensions and additions that are not found in other textbooks. One of the more useful features is Williams' emphasis on the differential impacts of alternative tax policies. For example, after determining the effect of a proportional income tax on work effort, the author immediately goes on to compare this result with the effect of a lump-sum tax of equal yield. The differential analysis is undoubtedly the most useful approach to tax questions and, unfortunately, is rarely used. The chapter on the income tax goes beyond the usual discussion of the proportional income tax and deals with progressive rate structures and the complications that arise when incomes are unevenly distributed through time. Also, in treating the impact of government expenditure on different economic agents, Williams provides new insights on a question that is barely mentioned in most textbooks on public finance.

The most ambitious parts of the book relate to the study of the differential effects of proportional expenditure and income taxes, and taxes on wealth of equal yield. These questions involve three dimensions, and Williams uses two approaches, a one-period analysis where the three variables are income, consumption, and leisure, and a three-period analysis where before-tax incomes are taken as given. Some writers, Kaldor being most notable among them, maintain that savings will be increased under an expenditure tax. Williams shows that this proposition is nonconclusive and that savings may or may not increase if a proportional expenditure is substituted for a proportional income tax of equal yield, depending on relative preferences for savings, consumption, and leisure. Williams also arrives at the interesting result that, in the case where saving is highest under the expenditure tax, there is no guarantee that this tax is superior on grounds of individual welfare. The welfare implications are obtained through the use of the basic axiom of revealed-preference analysis. The author is quick to point out that his results are very tentative, limited as they are by one-period analysis. The comparisons of a wealth tax with expenditure and income taxes are also nonconclusive.

The chapter on general equilibrium aspects of budgetary policy is conducted in terms of a two-factor, two-commodity model.

Discriminatory taxes destroy the equality between the marginal rate of transformation in production and the marginal rate of substitution in con-

sumption. The distribution of income depends on the output-mix of the economy when the production functions are of different factor intensity. Also, when the two groups have different spending propensities the effect of any tax or expenditure policy will depend on a complicated interrelation between source of income and use of income considerations.

The basic objection to Williams' treatment of this area is his frequent use of a highly dubious analytical procedure often used in the literature, in which it is assumed that taxes are collected and then returned to taxpayers in the form of lump-sum subsidies. The usefulness of this device presumably depends on some notion of a tax illusion which would make the taxpayer unaware of the fact that the subsidy he receives is exactly equal to the taxes he pays. Otherwise it is difficult to see why a tax on a particular commodity should change the pattern of demand, as demonstrated by Williams, while an income tax will not. Why should an informed taxpayer change his demand for food if he knows that the size of the accompanying subsidy depends on the amount of food he buys and is exactly equal to the tax he pays? More generally, the chapter is disappointing as it is an indication of the underdeveloped state of the general equilibrium approach to budgetary questions. There seems to be no advance beyond such statements as the one found on page 217:

... we might say that some will be better off under the indirect tax, and others under the direct tax. It should be added that it is quite conceivable that both groups would be worse off under the direct tax. ... It depends to a large extent upon the relative magnitude of the income shifts due to factor price changes compared with the effects on consumption through price changes.

The problems are, of course, complex, yet the lack of progress is in large measure due to the shortcomings of graphical analysis. The alternative approach is algebra, which often yields expressions so complicated that they defy qualitative interpretations. However, Harberger's recent work on the incidence of the corporation income tax shows that an empirical application of such results can yield fairly definite conclusions or at least narrow considerably the range of possibilities.

*Public Finance and Budgetary Policy* is in some respects an incomplete and uneven book. There is no distinct treatment of tax incidence. The sections on stabilization policy and growth are thin relative to other parts of the book, and the difficulties associated with choosing a government budget of the "right" size and composition are by-passed. Furthermore, the complete lack of institutional and empirical material weakens the usefulness of the book as an introductory text. Yet, Williams' contribution would probably have been less significant had he tried to be more comprehensive. For by limiting his range he comes to grips with a number of complications and special cases that are by-passed even in the more advanced treatises. Williams has produced a valuable addition to the very small number of competent books on the theoretical aspects of tax and expenditure policy.

*The United States Balance of Payments in 1968.* By WALTER S. SALANT AND OTHERS. Washington, D.C.: The Brookings Institution, 1963. Pp. xvii, 298. \$5.00; paper, \$2.95.

Ours has been called the age of the critic. None should find this designation more apt than Walter Salant and his co-authors of the "Brookings report." Their attempt to forecast the U.S. balance of payments in 1968 has drawn a flood of comments, including a Joint Economic Committee hearing and a compendium containing no less than 68 statements,<sup>1</sup> as well as those in the standard reviewing media. Probably the ratio of critical and exegetic pages to pages in the original run up by the Brookings report approaches that of Joyce's *Ulysses*.

Long-run forecasting of the balance of payments is, as the authors note, an especially difficult task. When you forecast GNP six years hence, you are fairly sure that it will increase. But the balance of payments is a sum of pluses and minuses, and the chances of getting a forecast with a reasonable confidence interval (assuming, contrary to fact, that long-run forecasters use standard errors) which lies on one side of zero are small indeed. Yet policy decisions relating to payments disequilibria need to rest on the expected future situation and not on past history alone. Furthermore, the one major previous attempt to forecast the U.S. balance of payments, published in 1957 by Sir Donald MacDougall,<sup>2</sup> concluded correctly that the U.S. balance would deteriorate if other countries succeeded in keeping the movements of their price levels in line with that of the United States; however, he largely threw away this conditional forecast by regarding such price restraint as unlikely. Apparently, balance-of-payments forecasting is both necessary and possible.

The Brookings study focuses upon the so-called "basic" balance, excluding short-term capital movements. The underlying model is as follows. Current-account transactions (except interest and dividends) depend mainly upon the growth of GNP and changes in the price levels of the United States and Western Europe, with the exact relations drawn from equations fitted by Polak and Rhomberg of the IMF to 1948-60 data. The authors ingeniously simplify their task by assuming that no significant changes will occur in the international reserves of other areas. Thus, no net changes take place in the over-all balances of "third" countries, and any changes in their international transactions with the United States are then assumed either to leave the U.S. basic balance unchanged or to wind up affecting the basic balance of the Western European countries. Outside of the current account, the balance

<sup>2</sup> Donald MacDougall, *The World Dollar Problem: A Study in International Economics*, London 1957.

on long-term capital is estimated from prospective changes in returns to capital and in gross foreign assets here and abroad. U.S. government military and aid transactions are based on projected plans of the government agencies involved. Throughout, considerable care is taken to include the indirect effects, or "feedbacks," of changes in a given class of transactions upon other elements in the balance of payments.

Besides the structure of the model itself, a major question concerns the estimation of the independent variables for these functional relations. Operating under instructions from the Council of Economic Advisers, the Brookings group assumed that U.S. GNP will grow at 4.8 per cent annually between 1960 and 1968, in conformance with government growth objectives; furthermore, the Council specified the assumption that prices (the implicit deflator of GNP) would rise at 1.5 per cent annually. The GNP increase for Western Europe was also drawn from stated policy objectives rather than independent projections, in this case the average of the "plan targets" submitted by the European nations to OECD. The behavior of European prices, an annual increase in the GNP deflator of 2.75 per cent, was deduced in the light of the growth in productivity per worker necessary to achieve the GNP growth objectives and the changes in money wages and the distribution of income which might be expected to accompany the growth of productivity.

This use of government targets for GNP growth, as well as the plans of U.S. government agencies for economic aid and foreign military expenditures, makes the Brookings estimate a highly conditional one. The authors themselves found these official targets "rather optimistic," and developed a projection based on alternative assumptions of the same inflation but slower growth for the United States, and less of both growth and inflation for Western Europe. (The authors also feel that projected U.S. economic aid is too high, but a reduction of this forecast would have had little effect on the predicted balance, once all feedbacks are taken into account.) The alternative assumptions give rather different results from the initial ones, and the difference has considerable importance in interpreting the Brookings conclusions. Under the initial high-growth assumptions, the U.S. basic balance improves to a surplus of \$1.9 billion in 1968; under the alternative assumptions, it remains in deficit, but only by \$0.6 billion. But the basic deficit was only \$0.8 billion in 1961, although \$2.1 billion in 1962, and \$2.4 billion through the first three quarters of 1963. The alternative projection is not much of an improvement, and it matters considerably which one we take.

Most of the difference between the projections based upon the initial and alternative assumptions is due to the differing rates of inflation. This fact causes concern about the basic statistical inputs, since the Brookings group had to use a large amount of guesswork in setting a price elasticity for European imports from the United States. In any case many commentators have declared that the Western European countries would never accept the rate of inflation associated with the Brookings initial assumptions. Yet the inflation rate is deduced directly from the assumed growth rate of real GNP. This view really asserts that the Brookings alternative assumptions are the right ones to take. Given the general tone of the authors' discussion, one might ex-

pect the Brookings group also to come down with the alternative projections as their unconditional forecast. But they do not: "Our best guess is that the basic deficit will be eliminated. If the initial assumptions come close to being realized, there is a definite possibility that a significant basic surplus will develop" (p. 230). Given both the uncertainty about actual domestic and export prices, as well as the uncertainty about the values of the crucial price elasticities, it seems wiser to take the Brookings estimates as suggesting an improvement in the basic balance by 1968 rather than as suggesting elimination of the basic deficit.<sup>3</sup>

This issue of the interpretation of the Brookings findings takes on great significance as we turn to the report's concluding chapter on policy findings, an addendum to the original report prepared for the Council of Economic Advisers. Noting that the United States still holds large usable reserves, if the gold reserve requirement against Federal Reserve notes were suspended, they recommend that no further steps be taken to improve the U.S. balance aside from measures which are desirable for their own sake. This recommendation is stated flatly (p. 253) despite the small minimum improvement under the alternative assumptions and the authors' view that the favorable trend may not show up until 1965 (p. 231). While they state eloquently the case for increasing international liquidity (coming close to the Harrod position that desirable domestic policies should never have to be disturbed to protect the balance of payments), they also give blessing to the progressive hardening of the "adjustable peg" of Bretton Woods into a system of absolutely fixed exchange rates. This choice of an unlikely over a likely corrective, for a problem which shows small signs of solving itself quickly, sounds like a dangerous compounding of probabilities.

Whatever one makes of the policy conclusions from the Brookings study, the basic analytical work deserves considerable respect for its unusual care in keeping track of the interrelations and feedbacks among variables. It does not, however, go all the way. The decision to concentrate on the basic balance excludes short-term capital movements from consideration, although recent statistical work has suggested that they interrelate significantly with the current account through export financing. More fundamentally, as Harry Johnson has pointed out, the model suppresses the monetary and financial structure of the economies in question and the financial policies of their governments. Yet balance-of-payments equilibrium is basically a monetary phe-

<sup>3</sup> Powerful additional support for a less cheerful interpretation of the Brookings conclusions comes from a revision of the Polak-Rhomberg model, extending its data span to 1948-62 and altering some of the data sources. Using the coefficients of the revised model, the improvement in the U.S. current account from 1961 to 1968 comes out \$2.6 billion less than the Brookings estimate under the initial assumptions, \$0.8 billion less under the alternative assumptions. It seems doubtful that a full revision of the Brookings forecasts would show a favorable basic balance under the initial assumptions, and would certainly not do so under the alternative assumptions. Furthermore, the fact that the revised Polak-Rhomberg model affects the current account less under the Brookings alternative assumptions than under the initial ones may provide further support for putting greater weight upon the former. For details, see Rudolf R. Rhomberg and Lorette Boissonneault, "Effects of Income and Price Changes on the U. S. Balance of Payments," *I.M.F. Staff Papers*, March 1964, 11, Table 8.

nomenon. Monetary policies and short-term financial flows may adjust passively to changes in real variables and cost-determined changes in the general price level, but one can hardly be blamed for wishing to see this proved rather than assumed.

*The London Capital Market and Australia 1870-1914.* By A. R. HALL. Canberra: The Australian National University, 1963. Pp. xiii, 221. 30s.

This work is a doctoral dissertation written in 1951 at the London School of Economics and published in 1963 without substantial modification except for the addition of a brief theoretical postscript. The study is primarily concerned neither with "attempts to prove a particular theory of the mechanism of capital transfer" nor with "the effects of changes in the rate of flow on the course of events in the Australian economy," but rather with "the institutions responsible for raising capital in Britain and the factors on the supply side influencing the flow to Australia . . . as one aspect of the flow of British funds overseas." It is therefore likely to be of greater immediate interest to the economic historian than to the economic theorist, except to the extent that it serves the latter as a convenient source of facts and data to theorize about. The principal conclusion drawn by the author is that the interaction of events in the lending area, London, with events in the borrowing area, Australia, rather than the events in either area taken by themselves, must be taken into account to explain the international flow of developmental loans. There seems to be no reason to challenge this conclusion.

Chapters 1-3 survey the types of borrowers, the characteristics of the securities, and the classes of investors in the London capital market for the period of the study. New issues from domestic companies were relatively insignificant. Overseas lending was shifting from Europe to the less-developed areas in Africa, Australia, and the Near East. Increased use was being made of preference shares and debentures, denominations were being made smaller, and less emphasis was being placed upon unpaid shares subject to call, all of which tended to appeal to a wider range of investors. Growth in facilities for marketing large issues, e.g., underwriting syndicates, and the growing popularity of highly marketable securities favored overseas borrowers.

Australian borrowing in London is the subject of Chapters 4-6. Government issues, particularly for railroad construction, made up a large part of the total. Banks, land mortgage companies, and mining companies were also among the borrowers. The section describes temporal fluctuations and geographical shifts in investment from London and explains them in terms both of supply and demand considerations. Of particular interest is the relationship between Australian politics and British investment there after 1890. Anticyclical fiscal policies, such as public works (in which Australia led Western Europe and North America by some forty years), helped to sustain prosperity and hence the demand for capital. But the same policies aroused the suspicions of the British investor of the day, appearing to him as fiscally ir-

responsible, and therefore contributed substantially to the loss of favor which Australian securities, especially governments, suffered in London after 1900.

The book is clearly written, concise, well documented, and well organized, though slightly repetitive. To the reader primarily interested in broad analytical interpretation and in the building of theoretical models parts of the work can be somewhat tedious, though in view of the author's clearly stated purposes, this cannot fairly be taken as a serious fault. The clear exception to this judgment is the eight-page 1962 "Postscript" (Chapter 8) which deserves special comment in spite of its brevity. It is a general statement (partly attributed to other writers) of the process of foreign capital investment in a developing country, including effects upon the terms of trade, the balance of payments, and the sequence of changes in the direction of investment within the borrowing country, especially between "traded" and "non-traded" goods. The analysis is applied interestingly, though sketchily and with qualifications, to the Australian economy for the period under study. Investment is first attracted by the comparative advantage of the land-using industries, e.g., wool and mining. The subsequent stimulus to other lines of economic activity, e.g., building construction, open new opportunities for investment, which, if extensive and persistent, may boost prices and wages, put exporters at a competitive disadvantage in foreign markets, and thus give rise to balance-of-payments difficulties, particularly after the inflow of foreign capital comes to an end. This effect may be retarded if the capital flow is accompanied by the immigration of labor, which keeps wages down. The analysis is not radically new, but taken in conjunction with the historical data at the command of the author, it suggests some intriguing possibilities for a more thorough-going integration of historical fact and economic theory.

*The Effect of Capital Structure on the Cost of Capital: A Test and Evaluation of the Modigliani and Miller Propositions.* By ALEXANDER BARGES. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1963. Pp. xii, 121. \$4.50.

Professor Barges' monograph, one of the five dissertations selected for publication in the 1962 Doctoral Dissertation Competition sponsored by the Ford Foundation, is both rewarding and disappointing. It is rewarding in that the author's investigation into the problems of measuring the relationship between the cost of capital and capital structure is more thorough than that of his predecessors. It is disappointing in that much of the theoretical discussion is devoted to a rather fruitless search for flaws in the logical structure of the Modigliani-Miller (M-M) argument. A more judicious and useful book might have been forthcoming if the author had been content to begin his theoretical exposition with the observation that the real world is much more complex than the world of the M-M propositions.

The empirical section of this work is the more significant contribution. Barges points out that where stock yield is regressed on the ratio of debt to

equity, the errors introduced by sample heterogeneity with respect to riskiness and size are nonrandom if equity is measured in terms of market value. The positive relationship between stock yields and debt-equity ratios that was found by M-M must, therefore, be spurious to some extent. To avoid these problems Barges proposes that regressions be run in terms of book value rather than market value. Such regressions will test the M-M Proposition II insofar as the only question asked is the existence or nonexistence of a positive relationship between stock yield and debt-equity ratios—not the size of the relationship. Using data from each of three industry samples (Class I railroads, cement companies, and department stores), Barges finds that the evidence for a positive relationship between stock yield and leverage tends to disappear when debt and equity are measured in book terms. For each sample the regression coefficients are not significantly positive. Furthermore, in each case such coefficients are less than the regression coefficients obtained from regressions on data given in terms of market value, although the statistical significance of the differences is not discussed. It is barely possible that Barges' findings can be explained in terms of a collinearity between leverage (in book terms) and risk, the firms with the lower debt-equity ratios also being the riskier enterprises in general. Yet whatever the true relationship, Barges has clearly shifted the burden of proof of Proposition II back to the M-M camp.

Barges' tests of the M-M Proposition I, the statement of the relationship between the average cost of funds and the ratio of debt to total value of the firm, are less conclusive. His regressions on the sample and various subsamples of Class I railroads suggest that the above variables are negatively related. While these findings are fairly straightforward, the conclusions to be drawn from them are not. It does not follow that an unambiguous finding of a negative relationship between the average cost of funds and the ratio of debt to total value of the firm makes the M-M position untenable. The null hypothesis that Barges should have tested in this case is not the simplest version of the M-M Proposition I but Proposition I as amended to conform to the realities of present-day tax policy. Since the amended Proposition I states that the average cost of capital is negatively related to the ratio of debt to total value of the firm, the relevance of Barges' findings to an investigation of the empirical validity of the M-M theorems is not clear.

Having shown that traditional hypotheses are more in accord with the observed data than are the M-M hypotheses, Barges proceeds to examine the theoretical basis for the M-M propositions. His main conclusion is that the M-M propositions depend upon a particular set of assumptions about risk preference. This conclusion takes two forms. The first is a restatement of the observation by Durand that the arbitrage process which M-M portray may involve an extension of the scale of the investor's holdings and thus a difference in the risk equivalence of the pre- and postarbitrage portfolios. This criticism applies to the situation in which the value of a levered firm is greater than the value of (an otherwise identical) unlevered firm. This is valid as an attack on the particular arbitrage scheme proposed by Modigliani and Miller, but it does not get to the heart of the matter since an alternative

arbitrage scheme can be suggested. If the owner of (overvalued) levered stock has bonds in his portfolio such that the ratio of his bond income to the income of his levered stock is at least as great as the ratio of bond interest payments to stockholder income for the levered corporation, the owner of the levered stock will find it to his advantage to sell a combination of levered stock and bonds and purchase unlevered stock. The necessity for margin borrowing which M-M foresaw derived from the tacit assumption that there was no portion of the portfolio of the owner of the levered stock that was not levered. Such an assumption is clearly too restrictive.

Barges' second attack on the theoretical bases of the M-M propositions amounts to a charge of overdeterminacy. Modigliani and Miller postulate a set of discount rates that the market deems compensatory for varying degrees of risk—risk being expressed in terms of mean-variance ratios. Yet, Proposition II also specifies a relationship between returns of various risk classes (stocks of differing degrees of leverage) that is apparently independent of this initial set of discount rates. What is to insure the consistency between the returns deemed appropriate according to Proposition II and according to the initial set of rates for the various risk classes?

The appeal of this argument derives from the fact that Modigliani and Miller chose to represent the rate of discount appropriate to a pure equity stream as a single rate chosen from the initial set of rates that specifies the market's reaction to risk. This is somewhat misleading. Let the postulated set of discount rates,  $r_0, \dots, r_n$ , be defined such that  $r_0$  is the rate of return appropriate to an income stream expected with full certainty and the rates  $r_1, \dots, r_n$  are appropriate to income streams that are uncertain, the outcomes being defined in terms of probability distributions that are characterized by differing mean-variance ratios. Further, let the probability distributions that are associated with the rates of return  $r_1, \dots, r_n$  be defined such that it is uncertain that a positive income stream will be forthcoming. Then any given income stream "X" can be understood as the sum of " $A + Y$ ," " $A$ " being a certain value and " $Y$ " being a stochastic variable defined by a probability distribution for which the least attractive income stream that is possible is zero. The rate of return appropriate to a pure equity stream is thus a function of  $r_0$ , the  $r_j$  appropriate to that part of the expected income stream that is uncertain, and the proportion of the expected income stream "X" that is uncertain. If both the rates of return to a pure equity stream and the rates of return to levered equity are thus understood to be weighted averages of rates drawn from the set  $r_0, \dots, r_n$ , the appropriate weights being established by the proportion of the income stream that can be expected with certainty, the spectre of overdeterminacy vanishes.

The most fruitful of the criticisms that Barges has leveled at the Modigliani-Miller constructs is the charge that the M-M Proposition II is a hybrid. That is, M-M have defined interest payments in current terms while payments to equity are defined in terms of expected value. This is an important observation and deserves following up, for it points up the fact that the M-M model does not deal with such complexities as the expectation of change in the structure of the rewards to risk-bearing, shifts in price expectations, and

changes in the distribution of price expectations among investors of differing attitudes towards risk. The M-M postulates give every appearance of being logically consistent, but they apply to a world that is notably simpler than the real world. Furthermore, they remain, even on their own terms, a set of normative propositions. Whether they are useful as positive propositions remains in doubt.

*Concentration in the Manufacturing Industries of the United States—A Mid-century Report.* By RALPH L. NELSON. Economic Census Studies, No. 2. New Haven and London: Yale University Press, 1963. Pp. xiv, 288. \$7.50.

This study was sponsored by the Committee on Analysis of Economic Census Data appointed by the Social Science Research Council. It is the second in a series of monographs based on the economic censuses of 1954.

More than half the book consists of tables of basic data prepared by the author. These include various measures of both company and plant concentration for a large number of manufacturing industries for the years 1947, 1954, 1955, and 1956. The concentration measures are based on value of shipments as the measure of both market size and firm or plant size, but concentration in terms of value-added, total employment, and production worker man-hours is also shown. In addition to these statistics based on "four digit" industries, concentration measures for "five digit" product classes are given, on both a company and a plant basis.

The first hundred pages of the book present descriptive and analytical findings, supplemented by a very thorough discussion of the methods used in processing the data and the problems that were met.

Ralph L. Nelson suggests that the well-known finding that large industries tend to have lower concentration than small industries reflects *in part* the tendency of statistical classification systems to make large industries more heterogeneous in the products and techniques they include than small industries. The greater heterogeneity of large industries is not actually demonstrated by Nelson but is apparently inferred from the fact that large four-digit *product classes* tend to have more five-digit subclasses than the small. Even this relation, however, does not necessarily demonstrate the greater heterogeneity of large product classes but could conceivably be due to the practical desirability of avoiding very small five-digit classes.

A comparison of concentration in 1947 and 1954 shows that the weighted average of concentration ratios changed very little indeed over the period, but that there were large changes in concentration ratios for individual industries. These results are very similar to earlier findings for the period 1935 to 1947. The changes in concentration for individual industries are negatively correlated with industry growth, but the correlation is weak.

In comparing plant and firm concentration Nelson finds that the leading firms tend to have both larger plants and more plants than the rest, but that while the tendency for leading firms to have more plants is more pronounced in highly concentrated industries, the tendency for leading firms to have larger plants is not correlated with concentration.

There is a minor error in Nelson's discussion of the importance of multi-plant operation in different industry groups (Table 4.3). He measures the number of plants "with sister plants in the same . . . industry" by subtracting the number of firms from the number of plants. This difference, however, only sets a lower limit to the number of plants "with sister plants in the same industry," and the actual figure may be quite different. If there are five firms and ten plants, the number of plants belonging to multiplant firms must be more than five. But it will be ten if each firm operates two plants, and only six if one firm operates six plants.

The book includes a fairly inconclusive study of the differential characteristics of the four leading firms in each industry and a discussion of the changing composition and characteristics of the 50 largest manufacturing firms.

Some of Nelson's statistical experiments seem unnecessarily cumbersome, and the style of writing does not make for easy or pleasant reading. The book as a whole, however, represents a valuable addition to the material on concentration available to research workers.

### Land Economics; Agricultural Economics; Economic Geography; Housing

*The Economics of Highway Planning.* By DAVID M. WINCH. Toronto: University of Toronto Press, 1963. Pp. ix, 158. \$3.95.

"This book attempts to extract from economic theory the best guidance available on [the highway planning and pricing] problems and to present it in a form which can be understood by the non-economist" (p. x). The first two-thirds of the study is devoted mainly to setting up an analytical framework for measuring highway benefits and for determining optimum investment programs. The remainder deals mainly with problems of allocating the highway-cost burden among groups of users, property owners, and the public at large.

As is the practice of most public agencies in analyzing their investment projects, only publicly borne costs are incorporated in the denominator of the benefit-cost ratios that highway engineers compute for proposed highway improvements. The numerators, then, are the savings it is predicted the improvements will afford their users. Winch objects to this approach. Since traffic volume is a function of trip costs, the traditional procedure makes it difficult to compare alternative plans involving different user costs. Also, it gives no clues as to the optimum traffic volume on a highway. He therefore proposes an approach which, in effect, recognizes that a highway user operates on both the supply and the demand sides of the market for trips. Un-

der his system, the task a highway authority should set for itself is to build that highway network which maximizes the area between demand and long-run marginal cost schedules, where "costs" include not only those borne by the highway authority but also the vehicle operating, time, and other costs sustained by highway users and the public at large.

In an appendix, Winch attempts to justify this advocacy of what is essentially a "competitive" highway investment criterion in light of the arguments of Lipsey, Lancaster, *et al.* against competitive pricing in some sectors when monopolistic pricing cannot be eliminated in others. The main points in his argument for a marginal benefit cost ratio of unity (in the long run) seem to be (1) that the resources involved in a highway investment program would be diverted mainly from sectors that are approximately competitively organized; and (2) that, contrary to the practices of the private sector, the highway authority would (or at least should) include such technological externalities as traffic noises and smells in its cost calculations.

In dealing with how best to distribute the burden of highway costs, Winch finds considerable fault with the melange of allocation principles involved in the highway literature. Where cost responsibility can be assigned to individual users or other members of the community, he advocates doing so. The remaining costs—by far the largest group, he suggests—should be allocated so as (a) to optimize the use of highway facilities; (b) to preserve "the normal balance of competitive forces" among transportation modes; and (c) to distribute the burden equitably among those who benefit.

For reasons that are never clearly specified (perhaps because he regards them as self-evident), Winch maintains that the system of trip-related charges—mainly gasoline and tire excises supplemented where feasible and desirable by direct tolls—necessary to achieve the closest realistic approximation to the first of these goals would not yield sufficient revenues to cover the costs of an optimum highway network. On grounds that "it is probable that more traffic would be discouraged in the form of marginal trips by all users than of marginal users altogether" (p. 137), he advocates relying on license fees rather than additional trip-related charges to make up the presumed deficit.

My principal substantive objection to Winch's study is related to this insistence that congestion tolls would cover only a small part of the costs of an optimum highway system. Congestion tolls are the analogue of the quasi-rents received by fixed capital in a competitive industry. In long-run competitive equilibrium, by definition, quasi-rents equal capital costs. Essentially the same consideration applies to highways. Congestion tolls would equal capital costs for an optimum system as Winch defines it *if* the production function for trips on a given highway involves constant returns to scale and *if* inputs were purchased on competitive markets. True, the limited available evidence does suggest that the real-world production function involves increasing returns. However, the cost of rights of way and other highway construction inputs seem typically to increase with highway size. While the former influence may well more than offset the latter, it is still by no means obvious that a substantial difference would exist between optimum trip-re-

lated charges and the costs of an optimum highway network. But even if Winch's view of the relation between these two magnitudes is valid, his "equity" and "competitive balance" standards would still militate against heavy reliance on license fees—discriminating, as they do, against infrequent users of highway services.

A large part of the first two-thirds of the study is devoted to sorting the effects of highway investments into "cost," "benefit," and "irrelevant" categories and to discussing ways of attaching dollar values to those costs (the value of travel time, in particular) that are not directly reflected in market transactions. The validity of most of his conclusions on these matters seems indisputable. Unfortunately, however, they are stated in a manner that is unlikely to convince the engineers that Winch numbers among his audience. For example, the highway literature is replete with claims that the increases in land value in the vicinity of improved highways should be added to the numerator of benefit-cost ratios. Dismissing these putative benefits with a bald statement to the effect that including them would entail double counting of benefits transferred from their initial highway-user recipients is unlikely to have much effect.

In brief, a considerable number of obstacles—not the least of which is the reluctance of civil engineers to accept the sage counsel of economists—stand in the way of applying the Winch analytical framework. Nevertheless, he has performed a valuable service by demonstrating that the partial equilibrium framework we use to analyze competitive markets can be employed without fundamental alteration to the highway investment problem.

HERBERT MOHRING

*University of Minnesota*

*Recursive Programming and Production Response.* By RICHARD H. DAY. Contributions to Economic Analysis, XXX. Amsterdam: North-Holland Publishing Co., 1963. Pp. xiv, 226. \$6.00.

The latest monograph in "Contributions to Economic Analysis," a series devoted to the practical application of economic analysis, is an exemplar of the "judicious blend of theory and fact" that its author, Richard Day, takes as his standard. The study reports on an extension of dynamic programming to a sequential optimization process. The application is to farm production data from the Mississippi Delta for nine crops. An area supply functional is estimated by explicitly taking into account the optimizing behavior of the firm decision-makers and their institutional as well as economic environment. Some topics of purely theoretical interest are introduced en route to the solution of the practical problem. But throughout the book, the goal of predicting the complex response of the region's farm output to market, technology, and program is kept to the forefront. Extensive data and technical problems are relegated to appendices where they are fully treated. Misprints are numerous but minor.

Day sets this study in perspective with other studies of supply estimation by pointing out that early procedures which statistically related the supply

of single agricultural commodities to prices and techniques were essentially short-run models. A more dynamic approach to farm supply was taken by Marc Nerlove, who adapted and applied the work of Koyck and Cagan on distributed lags to the estimation of long-run supply elasticities. James Henderson, on the other hand, explicitly recognized that production response underlies market supply and estimated the changing farm land use that would gradually adjust toward maximizing expected net revenues. A brief exposition of these two approaches is given in Chapter 1, and Chapter 2 extends the Henderson model into a class of dynamic programs by means of simple examples clearly explained. Chapter 3 develops the general properties of these recursive programs in a manner rather difficult for the nonmathematician. However, the material serves to demonstrate the abstract rationale for the specific problem attacked and to classify the model as dynamic in the Frisch-Samuelson sense, i.e., its evolution over time is determined recursively by the periodic changing of target functions and constraints.

The next four chapters present the method's application to data for the joint output of nine crops in the Mississippi Delta. Briefly summarized, recursive programming is exhibited as the period-by-period optimization of a net revenue target whose values are the amounts of commodity produced in the period (or acreage times yield) multiplied by the net per unit returns of each commodity lagged one period. The net returns can be related to product demand and input supply equations for a closed dynamic system. The optimization process is constrained by total land supply, acreage controls and, recursively, by coefficients of maximum and minimum adjustment to optimal land use and investment. Technology is represented for each period by a matrix of input requirements and output yields for each unit process level. Processes are classified for each crop combination by five technology stages (major types of input combinations), by 36 input categories, by three soil types, and by a continuously variable yield response function approximated by four discrete levels of nitrogen fertilizer application. The matrix contained 37 distinct processes from 1940-45 and 103 from 1946-57, with 1945 the approximate date of innovation for rice production, cotton-picking machines and self-propelled combines. Solution proceeds repetitively by solving each period's linear program on the basis of the initial conditions generated by the previous program or by the starting data. The model "predicts" acreage well but yield poorly, due mainly to what Day characterizes as the skewed effects of weather conditions. The study terminates with 70 pages of appendix, including data sources, estimation techniques, and a complete tabulation of model inputs and results. References are listed but no index is provided.

The author admits that taking no account of the random effect of weather on yield badly upsets the results. Yet, if the model is intended to predict rather than explain, nothing can be done unless there is evidence of nonrandom weather runs. Perhaps the model could have been converted to a stochastic one after it had generated acreage response to put confidence intervals on yields as they are affected by weather variation.

The coefficients of output and investment adjustment are key parameters of the model. Most of the multiple phasing is conditioned by these con-

straints which are exogenous to the model. Yet there remains some circularity in the method of their estimation. For each quantity assumed subject to an adjustment constraint, a subperiod is selected for which the upper or lower constraint is hypothesized to be operative. Statistical estimates are formed from this period and used in the recursive program. The program's results are compared with actual data and, if the "fit" is not good, new subperiods are chosen for selected quantities to form a second set of adjustment coefficient estimates. The iteration continues in the hope that the program will converge to what Day calls a "meaningful structure," namely, one that accurately predicts succeeding data from the starting conditions. Thus, theoretically, it is no longer a predictive model of producer reaction to change. It becomes a method for estimating those coefficients of producer flexibility and innovation diffusion which best explain the actual response of producers under the other assumptions of the model. It is only fair to add that, due partly to the expense of numerous iterations, the above method was only repeated once to correct *ex post* for incomplete specification of the constraints.

In spite of these criticisms, this reviewer feels that the book is a worthwhile addition to the library of any research economist. Criticism and improved research are easy when rationale and results as well as data are laid honestly before the reader. The theory used has been generalized to an extent that makes it potentially applicable to many problem areas. The specific problem has been attacked with a care for detail and fact that is seldom observed in the writings of those proficient in complicated new techniques.

E. J. R. BOOTH

*Oklahoma State University*

*North Atlantic Policy—The Agricultural Gap.* By JOHN O. COPPOCK. New York: Twentieth-Century Fund, 1963. Pp. 270. \$4.00; paper, \$2.25.

John Coppock, now with the Food Research Institute at Stanford University, has done a much-needed analytical job. He has examined the agricultural policies of the European Common Market countries with reference to several considerations: the over-all economic, political, and military objectives of the Common Market; the wisdom of agricultural resource allocation within the Atlantic community; and the prospect for American farm exports to the Common Market countries.

With respect to all of these considerations, Coppock finds European agricultural policy to be unwise. "Protectionist," "autarkic," and "cartelized" are the words he uses. The case is best stated in the author's own words. Concerning over-all objectives he says, "European unity and greater Atlantic integration would be one of the great events of history. To jeopardize it, even to slow its arrival, by disagreement over agricultural policies is an act of political irresponsibility" (p. ix). On resource allocation he says:

It must be said that the management of Western agriculture . . . has been a failure. On the face of it, there are few economic phenomena to match in absurdity the piling up of huge surpluses of agricultural

products in the United States over the past decade; or the continued production of inferior wheat in Switzerland at about \$4 per bushel, when good Canadian wheat could be imported for about half that amount; or the ludicrous situation of Britain's dumping on the international market in 1957 some 100 million eggs (while importing even more), produced under a subsidy which probably accounted for all of the producers' net income derived from the sale of the eggs . . . (pp. 23-24).

On prospects for U.S. farm exports to Europe:

There seems to be little doubt that the agricultural industries of the European countries, under present policies or those likely to be adopted, are capable of expanding supply at a rate considerably in excess of that expected for demand. It would appear that output can easily be increased at a minimum rate of 2 per cent or more annually—almost double the anticipated rate of rise in demand. If this should take place, European net demand for imported non-tropical foods and feeds would be halved by some time in the late 1960's and would virtually disappear over the following decade (p. 173).

Thus Coppock sees a strong possibility that U.S. agriculture will lose its best export market, a cash market which has been accounting for more than a billion dollars worth of farm products annually. The data on which this analysis is based come from the Ministries of Agriculture in the various countries, from the Food and Agriculture Organization, from the Economic Commission for Europe, the Agricultural Division of the Economic Commission for Europe, and the Organization for European Economic Cooperation. The data have been handled with considerable care. Coppock is experienced in economic analysis, having co-authored (with J. Frederick Dewhurst and P. Lamartine Yates) the recent major Twentieth-Century Fund study, *Europe's Needs and Resources*.

Coppock attributes the prospective increase in European farm production to price policies, adopted for political reasons, which provide farmers with excessive inducements to increase output. He offers a corrective: reduced levels of price support. For example, he proposes that support prices for wheat be reduced below 1960 levels by the following percentages:

Switzerland	—45	Netherlands	—20
Germany	—35	Sweden	—20
Italy	—35	France	—15
Norway	—35	Denmark	—10
Austria	—30	Canada	—5
Belgium	—25	United Kingdom	—5
United States	—23		

Price reductions of this magnitude would be expected, Coppock says, to deter wheat production in most of the countries of Europe. In the United States the effect would be to reduce wheat production somewhat. There

would be no deterrent effect in Canada. The effects on farm income of such changes, says Coppock, "generally are not catastrophic" (p. 200).

The book is well organized, is quite readable, and is amply stocked with well-composed tables.

What can one say of Coppock's diagnosis? This reviewer agrees that the Common Market may indeed founder on agricultural policy. He agrees that the allocation of agricultural resources in the Atlantic community is irrational. However, though impressed with Coppock's scholarly work, he is unready to concede the loss of the U.S. farm export market in Europe. He doubts that, even with the inducements supplied by European farm policies, the farmers of Europe would, simultaneously, feed more people, upgrade diets, and replace imports from the United States. Admittedly, hope may be an ingredient in this judgment. The directional effect on production and trade of autarkic agricultural policies is clear enough, although there may be some dispute as to the degree of influence.

Whether the economic sanity and political courage needed to effectuate Coppock's remedy are to be forthcoming is a judgment left to history. In any case, Coppock has done a piece of work that deserves reading on both sides of the Atlantic. The Twentieth-Century Fund has again demonstrated that economic analysis is a necessary, though not a sufficient, ingredient of wise policy formation.

DON PAARLBERG

*Purdue University*

*Housing Markets and Public Policy.* By WILLIAM G. GRIGSBY. Philadelphia: University of Pennsylvania Press, 1963. Pp. 346. \$6.50.

Focusing on selected aspects of housing market analysis which have a direct bearing on housing and urban renewal policies, William Grigsby's book makes a significant contribution. In a field in which market-oriented studies often by-pass policy implications while policy-oriented writings tend to ignore or misunderstand the allocation process through the market, such an integrated effort warrants attention.

In six chapters, the author examines the structure of the housing market, the much embattled "filtering" process, the movement of house prices and rents, some of the variables determining the level and composition of new construction, the maintenance and improvement of the stock of housing, and residential renewal. In nearly every one, Grigsby offers fresh insights or modifications of existing theories and questions the assumptions or objectives of public policy. The analysis ranges from what amounts to a careful crossing of *t*'s to the most comprehensive critique of the urban renewal program yet to appear in the literature. New empirical materials are drawn for the most part from comparison of the 1956 National Housing Inventory and the 1950 Census of Housing, including special tabulations for the Philadelphia area.

If the book leaves the reader with the impression of a series of fragmented, never-fully-integrated essays lacking in incisiveness or common methodology,

Grigsby disarms him by his modestly stated goal. The study is "tentative and exploratory and reaches no firm conclusions. It seeks instead to encourage analysts to view the market differently, pursue new lines of inquiry, and organize existing data in a different fashion" (p. 28). On the whole the author succeeds rather well, though often laboriously, in meeting these objectives.

Grigsby effectively uses matrix analysis to illuminate the interaction of housing submarkets and their demand and supply components, and flow analysis to trace occupancy changes in the various sectors of the market, as well as verbal or simple numerical models. The dynamics of the supply of existing dwelling units, an often neglected subject, is thoroughly analyzed with reference to Census data. As for the performance of the allocative functions of the housing market, the author takes a position, on the whole well reasoned, between the housing reform literature and the *laissez-faire* school (although his performance standards are never made explicit).

Many readers will have reservations on detail. For example, Grigsby seems to place excessive reliance on 1950-56 data for the development of generalizations. Among other things, rents in 1950, the base point of the analysis, were still at controlled submarket rates in most places, even though, as pointed out in the book, control was gradually abandoned during the next few years. Similarly, the finding that "a large portion of the stock . . . improves with age" may reflect conditions unique to the 1950-56 period. This reviewer was more enlightened by the empirical test in Chapter 4 of one concept of filtering (rent or price movement relative to family income change) than by the somewhat diffuse theoretical discussion of the subject in Chapter 3. He was also disappointed by the occasionally premature termination of analysis pertinent to Grigsby's purpose. Considering the reallocation of income in favor of housing, for example, he raises the familiar question of the benefits of alternative income allocations, notes that the question has not received the attention it deserves, and proceeds by giving it no attention either (pp. 304-5). But these blemishes do not detract from the value of the book as a stimulating research document.

By far the most solid chapter deals with residential renewal. Among other things, the author questions the need for the subsidized land "write-down" in the present renewal program, especially in cases of nonresidential redevelopment; highlights the conflicts between national and municipal renewal goals; and points up the lack of rational policy for distributing federal aid, with the result that the program tends "in the direction of pure pork barrel" (p. 327). The dislocation of existing slum dwellers is viewed as a highly inequitable distribution of the burden of the program. "Redevelopment, which was intended to focus upon families least able to cope with their urban environment, has instead distributed its largesse upon all but that group, and indeed forces upon those who need help the most a form of regressive taxation unequalled in American history" (p. 325). In brief, Grigsby calls for thorough reconsideration of the program.

### Labor Economics

*Real Wages in Soviet Russia Since 1928.* By JANET G. CHAPMAN. Cambridge: Harvard University Press, 1963. Pp. xiv, 395. \$12.00.

This beautifully careful monograph covers "real wages" (i.e., the incomes from official employment and social services, less taxation and net forced loans) of nonagricultural "workers and employees" (i.e., every earner not a peasant, a state farm worker, a soldier, a forced laborer, or, possibly, an artist). It is most definitely *scuola di Bergson*: comprehensive, fair, exact in its definitions, up-to-date in its methods. So scrupulous is the author that she has most unfortunately refused to go beyond 1954, except for a few bare statements; so that she does not illumine one of the most important of all periods.

Chapter 10 is a good discussion of the place of real wages in the national income. Truth to tell, real wage per worker is just one of those inconveniently "full boxes" in economics. It is a long way from consumption per head of population and is frequently quoted in place of the latter through mental inertia alone. We have always used it, and anyway it emerges easily from the statistics commonly collected. Consumption per head is the interesting "box," empty for about a century after the beginning of serious economic statistics.

Real wages are of course indispensable in labor economics: we could not analyze collective bargaining, incentives, or leisure preference without them. But their relevance for macroeconomics has always seemed to me exaggerated, owing to Keynes' original obsession with the question. And Janet Chapman's book is not about either of these subjects but about welfare. It would then in a way be correct to say that she has used the wrong concept throughout. In her case, however, the excuse is undeniable: otherwise she would be in the morass of peasant incomes, and could only keep afloat on a book twice as big.

Now in market economies, even underdeveloped ones, real wages will probably move in fair sympathy with consumption per head. For the social wage and the taxation of the poor are small, and the free labor market is likely to preserve a constant inequality between wages and rural incomes. Labor force participation, trade union strength, and indeed the whole economy are subject to no sudden change. Not so in the USSR; not only must Mrs. Chapman modify her concept for taxation and the social wage, she must also show its relation to consumption per head. She has principally to deal with (1) the proportion of workers to dependants in a family, (2) peasant migration and peasant incomes, and (3) the division of the social wage between peasants and workers.

Consumption per head has held up very much better than real wages in the USSR, partly because so many more women work than used to in 1928. In this connection there is crying need for a domestic or consumption economist to turn her mind to the USSR. Despite her sex the author has not concerned herself with the consequences for true ultimate welfare or, for

that matter, true final output of the nonperformance of housework. We do not eat tin cans, we eat food cooked on the plate. Housework is production. What we buy in the stores is not final output, and I do not hold our indices of consumption per Soviet head to be truly comparable to Western ones, especially in 1928-37, when the real decline in housework took place.

As to the peasants and townward migration, although both peasant real incomes and real wages fell in 1928-37, consumption per head rose considerably (p. 166). Mrs. Chapman deals very well with this, though she might have generalized more explicitly the paradox that two quantities can both decrease while their average rises. Using particular symbols to illustrate the general case, this occurs when, in a static population,

$$\frac{Uu + Rr}{U + R} < \frac{(U + M)(u - k) + (R - M)(r - j)}{U + M + R - M}.$$

I.e., if we weight the urban and rural incomes  $u$  and  $r$ , obtaining in 1928, by their respective populations, the average can be less than that of smaller incomes  $u - k$ ,  $r - j$ , obtaining in 1937, if there is migration  $M$  to the towns and the migrants gain enough. This can be seen to be possible since it follows that:

$$(R - M)j + Uk < M(u - k - r);$$

i.e., the losses of those who remain in the countryside and the towns are less than the increase in the total income of the migrants; which is entirely possible if the original disparity  $u - r$  was great enough (it may have been equal to  $r$  in 1928.<sup>1</sup>)

As to the social services, not all of them are a social wage since a part—a shockingly small part—is paid out to peasants (pp. 128, 135). In the excusable absence of Soviet statistics on this point, Mrs. Chapman's division is rather arbitrary. No likely error here would affect her general orders of magnitude, but at few points is it more clear how "impure" a concept the real wage is from a welfare point of view.

The book contains rich factual information on social services, taxation, housing, rationing, the different kinds of retail market, etc. There are also some interesting technical points, not enough appreciated by practitioners in this field. Thus an index of money incomes divided by a Paasche price index yields a Laspeyres real income index, and vice versa (p. 30). The author also turns her attention, all too briefly, to the problem of hedonic price indices. A new good, she says, entering consumption between the base and the given year, could in theory be incorporated in an index by giving it such a base-year price as would have *just* rendered its consumption equal to zero (p. 33). But why "just"? Why is a price much greater than that incorrect? After all there is supposed to be only one price compatible with the consumption of a positive quantity, but infinitely many prices are compatible with zero consumption, and it is not obvious why the lowest is the most significant.

<sup>1</sup> If the population changes,  $U$ ,  $M$ , and  $R$  on the right-hand side of the first equation can all be raised or lowered by the same fraction. We can then proceed as before.

But still, there was seldom a happier marriage of theory and practice than in this book.

*"Disguised Unemployment" in Underdeveloped Areas with Special Reference to South Korean Agriculture.* By YONG SAM CHO. Berkeley and Los Angeles: University of California Press, 1963. Pp. xvi, 163. \$3.75.

In this book the author's objectives are three: to study critically the prevailing concepts of disguised unemployment in underdeveloped economies in search of "a more valid concept and theory"; to devise and apply to South Korea a method for "measuring true surplus labor"; and to study the policy implications of the empirical results. In the pursuit of these goals, he provides much interesting criticism of the current literature and a number of enlightening insights into the problems that arise when a specific area is subjected to study. Nevertheless, perhaps as a result of the inherent complexity of the subject, the book does not always live up to the aspired precision, nor are the three major sections integrated altogether satisfactorily.

In his theoretical sections, he accepts the standard definition of the concept of disguised unemployment, that is, the existence of applied labor with a marginal productivity of zero. He is, on the whole, unimpressed with the traditional literature on the subject, from the early work of John Lossing Buck to more recent writings of Nurkse and Lewis. As noted by Viner, Buck's data were inadequate to illustrate a marginal productivity of zero in the Chinese economy. The Navarretes' concept of disguised unemployment arising from cyclical fluctuations in demand (p. 13) "does not seem to be very helpful as a means of distinguishing unemployment in underdeveloped countries from that in economically advanced countries." Nurkse's work is held to be inconsistent with the facts, and his book is open to criticism (p. 17) on the ground that social institutions and congested population "may be the causes of visible idle labor, rather than the causes of so-called disguised unemployment."

These detailed criticisms of the literature are, however, primarily a background for Yong Sam Cho's major attack on the traditional treatment of disguised unemployment, which rests on a fundamental theoretical difficulty inherent in the concept. Specifically, he would like to know (pp. 4, 29) if the people of the underdeveloped world are "really so irrational as habitually to apply labor unnecessarily," that is, to work when the marginal product is zero. Cho's answer is clearly no. Therefore, when he turns to his study of Korean data, he concentrates not on "disguised unemployment," but rather on an alternative source of surplus labor, that is, those who constitute the part-time overtly idle. Thus, the quotation marks in the title of Cho's book are important. This dismissal of the traditional concept of "disguised unemployment" may, however, be looked on with some misgiving. Cho's simple reiteration of the irrationality of work resulting in a zero marginal product is not a conclusive case against authors who have argued that social institutions may develop to perpetuate this type of irrationality. This section on

the theoretical literature raises many questions that need to be answered, but Cho's attempts to do so are not always as tight and precise as they might be.

Before leaving the theoretical arena, the author discusses with approval the model based on the wage-working vigor relationship which has been developed by Leibenstein and others. Because of the malnutrition of those in underdeveloped countries, labor hours are not a homogeneous input; a worker's productivity may be expected to rise as his level of consumption rises. On the whole, this section is reasonably clear. However, because of the importance of the proposition in his general treatment of "disguised unemployment," Cho might usefully have explained in greater detail how this model illustrates (p. 42) that "the marginal productivity of employed workers is positive." Specifically, the reader may wonder why he arrives at a result in line with his earlier skepticism regarding "disguised unemployment," when Leibenstein, with the same basic model, came to the contrary conclusion that "landlords, as a group, are in an improved position if institutional arrangements permit them to employ the entire labor force . . . and yet not utilize the entire labor force" (*Economic Backwardness and Economic Growth*, p. 75). In my opinion, Leibenstein's use of the model is more open to criticism than Cho's; yet Cho has an obligation, which he leaves unfilled, of explaining why there is a difference on a matter of central importance between his conclusion and those of Leibenstein, whose model forms the basis of Cho's discussion.

Given Cho's emphasis on the theoretical implications of the wage-working vigor relationship, it is disappointing that this subject is not given detailed consideration in the empirical chapters, and this is particularly so because the author's medical training provides a suitable background for such a study. In spite of this shortcoming, however, the empirical chapters are among the best in the book and provide a significant contribution to our understanding of labor problems in the agricultural sector of a specific underdeveloped country. Cho estimates the surplus labor as the difference between labor available and labor employed. His conclusion is that unemployment is a seasonal phenomenon: during certain particularly busy times of the year, there is actually a shortage of labor in the sense that there is more work to be done than can be comfortably accomplished by the manpower available. These empirical chapters give evidence of being carefully developed; nevertheless, the results perhaps suffer from overadvertisement. The inherent difficulties of the subject must lead to skepticism regarding Cho's claims to have found the "true surplus labor" or a "reliable standard for the measurement of withdrawable surplus labor." Because workers who are idle at some periods during the year are needed at others, the terms "withdrawable" and "surplus" are themselves not very precise.

This difficulty is in large measure recognized when the author turns to the policy suggestions of his study, which hinge around the use that can be made of the seasonally available labor in the agricultural areas themselves. While these policy conclusions may usefully serve as a basis for further discussion, they raise certain problems. For example, it is not clear that his pro-

posed high rent tax aimed at pushing down agricultural land prices and causing the virtual extinction of absentee landownership (pp. 133-34) would be significantly less disruptive than outright confiscation.

*University of Maryland*

*Some Aspects of Wage Theory and Policy.* By SIDNEY WEINTRAUB. Philadelphia: Chilton Books, 1963. Pp. xi, 254. \$7.00.

Professor Weintraub deals with those aspects of wage theory and policy which are involved in a Keynesian-type aggregative model of income, employment, and prices. The price level receives most attention, and the principal argument is that *changes* in the price level are *caused* by changes in money wage rates. In brief, the book makes the case for a cost-push theory of inflation where unions push wages and wages push prices. The familiar dilemma is posed: How to reconcile the goals of full employment, price stability, and collective bargaining of wages? Weintraub concludes that the goals are in conflict and that negotiated wages must be replaced by a program of wage controls by a government agency.

The orientation of the book is, then, toward the current policy issues of inflation, unemployment, and "administered" wages and prices. Although Weintraub is carried to his policy position by his theoretical model, the case for wage controls could rest on other theories of wage-push inflation. This is worth noting because the theory in this book is rather sketchily presented. There are footnote references to the author's other published works for "more extended treatment" of the theoretical points, but here I would suggest that the criticisms of Weintraub's theory which Abba P. Lerner has made in a review of a previous book should also be examined by the reader.<sup>1</sup> There is still the tendency in this book to present macro-equations as definitions and then to confer them with behavioral significance which is supported, if at all, by meager empirical evidence or simply by the author's assumptions. For example, in Chapter 1 the main point made is the importance of wages and salaries in the consumption function and aggregate demand. But this "importance" simply stems from labor's large share of national income and from Weintraub's *assumptions* that (1) rentiers have near-constant incomes and consumption expenditures in the short run, and (2) wage earners and profit receivers spend 95 per cent and 50 per cent of their respective incomes on consumption.

In one of the equations of the macro-model presented in Chapter 2 the price level is defined as the quotient of average labor costs per unit of output divided by labor's share of output. Since labor's share is held to be constant, it is labor costs that alter the price level. Of course, one could just as accurately substitute the word "capital" for "labor" in the phrases above, but the author is setting the stage for the role of unions so labor costs are the focus of attention. He has already stressed the importance of wages in

<sup>1</sup> Abba P. Lerner, "On Generalizing the General Theory, A Review Article," this *Review*, March 1960, 121-43.

aggregate demand, although no feedback effect from labor costs to aggregate demand is analyzed. The higher prices which follow rises in labor costs are financed, says Weintraub, by increases in velocity and/or increases in the money supply which the government is forced to make to avert unemployment.

The proposition that labor's share, when defined as the ratio of employee compensation to business gross product, is constant over short periods is defended in the next two chapters. The discussion deals with the arithmetical relations of wages moving with prices and employment with output, lending short-run stability to the ratio:  $(\text{wages} \times \text{employment}) / (\text{prices} \times \text{output})$ . There is nowhere in the book any analysis of labor's share in terms of production functions and elasticities of substitution, demand shifts among labor-intensive and capital-intensive goods and services, changing factor supplies, or technological progress that may be labor-saving or labor-using.<sup>2</sup> Nor does Weintraub assess the criticism that the constancy of labor's share may be a statistical artifact resulting from offsetting changes of the shares in the industrial components of the aggregative figure.<sup>3</sup>

In Chapter 5 the author portrays the decade of the 1950's as one with "chronic unemployment" (pp. 41, 150) and inflation. But unemployment was quite low by historic standards from 1951 to 1956, and in the last few years of the decade, as Weintraub admits, "the price level has behaved fairly well" (p. 229). Nevertheless, even the slow upward creep of the price level along with the recent (from 1958 onwards) rather high levels of unemployment do call for attention and explanation. There are several well-known hypotheses on the problem that Weintraub never mentions: a growing "structural unemployment" that is not absorbed by increases in aggregate demand, the Gurley-Shaw explanation of rises in velocity (and the price level) stemming from the recent growth of money substitutes, and the charge made by Richard Ruggles and others that the price index is biased upwards.

In Chapter 6, which comprises nearly a third of the book, Weintraub advocates a program of wage controls that would, if necessary, require mandatory wage terms of all contracts involving 2000 or more employees. The tripartite governmental board administering the controls would be guided by average productivity increases, although consideration would be given to areas and industries with either labor surpluses or deficits. The latter proviso raises the problem of determining when a shortage or surplus of workers of some specific type exists (a much more difficult task than counting job vacancies and unemployed workers) and of how much of a wage change is necessary to achieve equilibrium. The controls would be over money wage terms of the contracts, and the problem of how to control supplementary or fringe benefits is inadequately discussed in a footnote (pp. 224-25). The

<sup>2</sup> Weintraub's reference to Irving Kravis' excellent article on this subject (this *Review*, Dec. 1959, 917-49) does not, in my opinion, excuse the author's failure to analyze the forces determining labor's share.

<sup>3</sup> See Robert Solow, "A Skeptical Note on the Constancy of Relative Shares," this *Review*, Sept. 1958, 618-31.

pros and cons of wage controls have been debated at length before, and I will not add my (largely negative) thoughts.

One final reservation to the *raison d'être* of the program concerns the validity of a *union-caused* wage-push inflation. Weintraub never mentions the many empirical studies of the effects of unions on both relative wages and on the absolute level of money wages. It is safe to say that the summary judgment of these studies would not support Weintraub's view of a crisis in our wage-setting procedures. A reader of this book should keep in mind that only about 25 per cent of the labor force is unionized, and that some of the industries experiencing wage increases that Weintraub points to as inflationary are largely nonunion. These points are not made by the author.

In conclusion, I do not believe Weintraub makes a convincing case on theoretical grounds for wage-push inflation nor for the efficacy of dealing with the current issues of full employment and price stability (the balance-of-payments problem is not mentioned) by means of a program of wage controls.

*Labor, Management, and Social Policy: Essays in the John R. Commons Tradition.* Edited by GERALD G. SOMERS. Madison: University of Wisconsin Press, 1963. Pp. xiv, 303. \$6.00.

This is a collection of ten papers commemorating the centennial of the birth of John R. Commons. The contributors are on the faculties of economics and law at the University of Wisconsin. Each has chosen a different subject. Two of the essays deal with Commons' approach to public policy and his "labor theory." The others mention Commons, in some cases only incidentally, in treating such diverse subjects as unions, collective bargaining, social insurance, migratory labor, prevailing wage law, and manpower analysis and policy.

As perhaps is to be expected in such a volume, the emphasis is more on Commons' views and on past developments than on new ideas or new approaches. Robert Ozanne attempts to rebut critics of the Commons-Perlman interpretations of union origins and "models" of union development, without, however, much success because no method for systematic testing of their rather generally stated hypotheses is presented, and some of the scattered assertions offered in rebuttal are questionable.

The article by Gerald Somers contains a good discussion of the problems of overcoming unemployment in depressed areas and of the role of retraining in the program. Based on research, particularly in West Virginia, it arrives at an interesting set of conclusions in a subject area largely neglected by economic analysis.

Collective-bargaining theory has suffered from lack of contributions beyond insightful, though untestable, assertions and rarified abstraction. However, Reed Tripp's treatment of the subject is too descriptive and diffuse to provide more than background material for a systematic body of theory.

The other essays offer a considerable amount of factual material but little in the way of economic analysis. The article on social insurance by Arthur Altmeyer does present a thoughtful review of developments and issues in that field by the former Commissioner for Social Security.

RICHARD A. LESTER

*Princeton University*

### **Population; Welfare Programs; Consumer Economics**

*Leisure Spending-Behavior.* By GEORGE FISK. Philadelphia: University of Pennsylvania Press, 1963. Pp. xix, 202. \$6.00.

Considering the economic importance of the subject, there has been little effort expended on the analysis of the determinants of the demand for leisure. Although the author of this study is aware of interest in leisure spending by economists interested in the dynamics of aggregate consumer spending, he writes primarily from the point of view of a professor of marketing. He projects aggregate demand for leisure goods and services to 1965 and 1970, defines market segments in terms of economic and demographic characteristics of families, and attempts to explain the segmentation by markets which he observes.

A useful feature is the assembly of data from three principal sources and the systematic comparisons of the concepts used in the 1950 Survey of Consumer Expenditures of the Bureau of Labor Statistics, the *Life Study of Consumer Expenditures*, of 1955-56, and the National Income Supplement. Much of the analysis is devoted to "total measured leisure," which is the sum of outlays for recreation, reading, alcoholic beverages, and foreign travel. While in 1960 this sum amounted to 9.0 per cent of disposable personal income, in 1946-47 it had been 11.0 per cent. It is hard to find evidence of a boom in leisure spending in these series. Even the increase in foreign travel from 0.4 per cent in 1950 to 0.6 per cent in 1960 is less impressive when one compares the level of 0.7 to 0.8 in 1929-30. Fisk guesses that total spending for "fun" may exceed 15 per cent of national income; there will remain uncertainty as to how this total is behaving over time until better statistical series are developed. It is clear that existing classifications of expenditures are not really satisfactory for studies of leisure or recreation expenditures.

By the time this review is in print interest in projections of leisure spending to 1965 based on data through 1958 will have little more than methodological interest. The method used essentially was to compute time-series income-elasticity coefficients from annual data for 1948-56 and for 1954-58 and use these coefficients to prepare two sets of estimates for 1965. Many statisticians are likely to have doubts about the usefulness of coefficients of income elasticity based on very short time series. No estimates of the standard errors of the regression coefficients are presented, but the two sets of income elasticities are very different. The discussion of the projections is complicated by the procedure of using per capita time-series income-elasticity coefficients as summary statistics for the combined change in tastes and income. Fisk then speculates about probable changes in the "income elastic-

ity" when what he clearly means are changes in tastes, to the confusion of at least one reader. Surely changes in taste can influence the constant term in a regression equation as well as the coefficient for income.

The cross-section analysis that makes up the bulk of the remainder of the book is likely to be more useful. Extensive cross-tabulations are presented with as many as three independent variables shown at a time. The findings are varied. It appears, for example, that Negroes spend less on total leisure than whites, allowing for differences in income and family size. Negroes seem to spend more on alcohol than whites, but this finding, like others concerning spending on alcohol, is rendered suspect because people on the average report only about 42 per cent of spending on alcoholic beverages. It may be merely that Negroes are more honest in this respect. People's spending on recreation appears to belong to that class of expenditures which is more closely related to their physiological age than to their stage in the family life cycle. This finding is consistent with other work which has shown that participation in outdoor recreation such as swimming, hiking, driving, and picnics is a function of age. (See the *Study Reports* of the Outdoor Recreation Resources Review Commission.) Per capita expenditures on "measured leisure" comprise only 4.3 per cent of income after tax for the income class over \$25,000 compared to 8.8 per cent below \$1,000, according to the 1950 Study of Consumer Expenditures. Can it be that "fun" is more attractive to low-income people? Or did the pleasures of the prosperous somehow escape unmeasured?

JOHN B. LANSING

*University of Michigan*

*The Economics of Welfare Policies.* By MARGARET S. GORDON. New York and London: Columbia University Press, 1963. Pp. xi, 159. \$3.00.

This volume is one of a series of three on the economics of health, education, and welfare, commissioned by the Ford Foundation. Both the Foundation and the author view the book as an introduction to some of the economic issues in the welfare area.

Dr. Margaret S. Gordon's preface indicates the purpose she hopes the book will serve: ". . . to stimulate interest in the economic issues associated with welfare policies, and to call attention to some of the important unsettled questions, rather than to provide an exhaustive discussion of all the problems." Time alone will tell whether interest is stimulated. If not, it would, perhaps, tell us more about our profession than about this contribution.

Dr. Gordon defines welfare programs as "social programs designed to transfer income in cash, in kind, or in the form of services, to those whose capacity for self-support has been impaired, interrupted, or (in the case of children) has not yet reached maturity." Health and education are excluded, however, and the focus is largely on income-maintenance programs. One might disagree on some of the items excluded and included under this definition (e.g., some portion of the veterans' programs), but the definition is workable. In any case, its greatest relevance is to the early and sketchiest part of the book. It does not affect the two chapters that comprise the bulk of the volume.

One can, perhaps, get a feel for the book's coverage and emphasis by listing the chapters (and their length): Introduction (5 pages); Welfare Programs in the United States (8 pages); Some International Comparisons (10 pages); Welfare Programs and Income Redistribution (7 pages); The Old-age, Survivors, and Disability Program (46 pages); Unemployment Compensation (40 pages); Conclusions (2 pages). Additionally, there is an Appendix describing provisions of the OASDI and Unemployment Insurance System (16 pages) and a list of references (totaling 226).

The text is largely concerned with a review of issues and previous research. The presentation is lucid and straightforward. Knowledgeable readers will find the discussion well documented and the list of references most helpful. Those who have not given much thought to the welfare area will find the book provocative and may be pleasantly surprised at the number of research questions that are suggested and the degree to which other areas of economic analysis impinge on issues in the welfare area. The book can, therefore, serve the graduate student in search of a dissertation topic as well as the professor who needs convincing that a topic in this area will require the use of analytic skills, knowledge of the literature in the mainstream of economics, quantitative techniques, and so forth. Obviously, too, it is sufficiently short to warrant the hope that others, as well, will read it and find new avenues of research opened up.

Perhaps, then, the book is best thought of as a research agenda (though an agenda which this reviewer feels fails to emphasize the cost-benefit analysis sufficiently). But how much more delightful to read this than to read a research agenda as such! For while the "agenda"—broadly defined—may be the volume's chief contribution, the discussion of issues and unsettled questions is interesting and stimulating in its own right. Perhaps Dr. Gordon would feel that if research were not stimulated the book would not have been worth writing, but it is certainly worth reading (even by those whose research time is "committed" but who want to talk more intelligently about public issues). If the reader finds the welfare area stimulating and wants to read further, he would do well to turn to Eveline Burns' book, *Social Security and Public Policy*. Both authors eschew the purely descriptive approach, emphasize policy issues, and raise analytical questions. The books are organized differently and have different points of emphasis. The one, therefore, does not serve as a substitute for the other.

One trusts that Dr. Gordon's hopes will be fulfilled and more economists will be concerned with the welfare area. Issues abound and decisions will be made—with or without the contribution of the economists. We need more researchers in the field—persons who, like Dr. Gordon, see the relevance of work in other areas of economics to the welfare area.

One also hopes that Dr. Gordon will write the longer volume on the economics of welfare programs that she speaks of in her preface. There is a need for many such books, and Dr. Gordon is one of a handful of persons who could write one of them.

*The Politics of Scarcity—Public Pressure and Political Response in India.*

By MYRON WEINER. Chicago: University of Chicago Press, 1962. Pp. xix, 251. \$5.00.

It is interesting to see how economists and political scientists working in the field of economic development have begun to turn to the questions of economic policy formation, with respect to economic problems in the under-developed countries. Within the past year Albert Hirschman's *Journeys Toward Progress* and Ray Vernon's *The Dilemma of Mexico's Development* have dealt with the adoption of certain specific development policies in various Latin American countries from an economist's point of view. This book deals with a similar range of problems (as well as others) in India from the viewpoint of a political scientist. (It is in turn strongly influenced by the Almond-Coleman book, *The Politics of the Developing Areas*.)

Myron Weiner's approach is quite different from that of the economists who are specific-policy-oriented; what he does is examine the role of pressure groups in India, and their relations to the government. After his general introduction, he identifies the specific pressure groups—communal, labor, business, peasant, and student—and discusses their aims, their membership, their hopes from the government, and their methods of exerting influence upon the government. He then discusses the response of the government to these pressure groups, presenting both a theory of the relationship between government and pressure groups in India and suggestions for improving the relationship. Ostensibly this is not an economic study; but in a country such as India, where one of the main responsibilities of the government is that of economic development, many of the policies of the government deal with economic problems, and very many of the specific functions of the government are to implement economic policies. Thus the main general problem that the book deals with is the role of interest groups in the making of economic policy in India. As such, it is unique in the literature of Indian economic development specifically and still rare in the general field of development.

I recommend for the economist especially those pages dealing with the attitude of the Indian population toward the role and tasks of government—an attitude which is not, I suspect, very different from that in other under-developed countries; the complex relations of business groups to political parties in both the formation of general policies and of specific administrative policies, and conversely, the popular and government attitudes toward business; the meaning and value of so-called "corruption" in a controlled economy; the power structure in rural India and the relation of peasant groups to farm policies and legislation in such fields as land reform, cooperatives, agricultural taxation, and other rural policies; the decision-making process in India with respect to the location of industries in the Plan—a discussion based on various examples. The treatment of each of these points was both highly informative and stimulating of other ideas and relationships.

Weiner concludes with a general thesis of the sharp dichotomy between government and politics in India—with the former essentially performing a largely administrative role, with its policies free from politics and based on rational analysis of what is desirable or optimal; politics, however, is irrational and “bad,” upsetting “the best” plans of government, and reflecting selfish interests. (A somewhat longer treatment of the reasons for this attitude would have been desirable.) Since the meeting ground between the “interests” and the government is a very narrow one, this leads, on the one hand, to an assumption of numerous functions by the government (since it considers it can do these best) and, on the other hand, to the acceptance of violence as a normal means of exerting pressure by the interest groups upon the government (since they have little other contact). One method that Weiner suggests to deal with this sharp split, a method of special interest to the economist, is to reduce the role of government by reducing the amount of direct control of the economy, and permitting greater scope for the market as a decision-making mechanism.

My main point of issue with the book is in fact with its general hypothesis of such a very sharp dichotomy between the government and the “interests,” with its assumption that the policies of the former are based on principles of economic rationality. While this is to some degree a hope on the part of the government, in fact the Plans *are* political documents and are prepared as such; and the broad economic policies of the Plans with respect to such topics as sectoral allocation of resources, sources of taxation, price policies, location of industry, etc., are strongly influenced by political calculations both within the Planning Commission itself and the Commission's parent body—the National Development Council. The Plans are *not* a product of an “above the battle” economically rational analysis (although this enters into the Plans) within the government, but they reflect argument and compromise within the bureaucracy preparing the Plans (both within the Planning Commission and the economic ministries); between the state governments and the Central Government; and within the Congress Party—and throughout this process political calculations weigh heavily. An interesting task for an economist would be to try to show how the various group ideologies and interests do in fact influence the macroeconomic character of the Plans and the implementation of the Plans—and thus the economic development in fact achieved in India during the past decade and likely to be achieved in the future. A related problem that the book deals with only peripherally is to what extent rapid economic growth is compatible with a government whose role is essentially that of an “honest broker” among various interest groups.

My general view of this book is that it is a most valuable and well-written contribution to the study of the politics of growth in all underdeveloped countries, as well as India, and I highly recommend it as such.

# NOTES

## POLICY STATEMENT ON ROLE OF THE A.E.A. IN ECONOMIC EDUCATION

Concern for improved economic education has grown during the past decade in every significant quarter. Leaders and rank and file among the general public, business, labor, the schools (at all levels), and the economics profession have become alerted and active. Increasingly, the interest and concern have been manifested in positive programs.

The American Economic Association has played a part in this movement. For a decade it has had a standing Committee on Economic Education. It has joined with others in sponsoring, or nominating members of, the National Task Force on Economic Education, the national television program "The American Economy," a Materials Evaluation Committee, a Committee on Measurement of Economic Understanding, and a Publications Advisory Committee to the Joint Council on Economic Education. Through its Committee on Economic Education, it established a special committee to prepare and publish a report on economics in secondary school textbooks on economics, social studies, and American history. The Association is formally affiliated with the Joint Council on Economic Education, nominates three members of the Council's board of trustees, and is prepared to cooperate with other responsible groups working to raise the scientific quality of economic education.

The economics profession has a responsibility second to that of no other group for the improvement of economic education among our present and future citizens; and the American Economic Association, as the body representing the profession, is now moving to step up its activities in this area and to assist its members to discharge that responsibility. The Association firmly disavows any purpose to determine or promulgate "authorized" economic doctrines or policies. It will, however, through its committees and interested members, undertake to make professional guidance and assistance more readily available to those who seek it.

Other professional associations in the social sciences, notably the American Historical Association through its Service Center for the Teachers of History, have shown the way. The American Economic Association has an experienced, responsible, and competent associate—the Joint Council on Economic Education—and other supporting organizations are at hand. Teachers, schools, and school systems at national, state, and local levels are asking for professional assistance, and members of the Association who are prepared to provide assistance need the leadership, coordination, and support that the Association alone can give.

In line with the foregoing, the Executive Committee of the Association has voted to reconstitute the Committee on Economic Education, with a mandate to move actively to develop a positive program to help improve economic understanding, and has approved an arrangement under which three members of the new Committee will serve as a special advisory committee to the Joint Council on Economic Education. This arrangement does not in any way make the Association responsible for actions of the Joint Council, but it will provide close, effective liaison, and will provide the Council systematically with outside counsel from professional economists.

The new Committee on Economic Education consists of G. L. Bach, Carnegie Institute of Technology; M. R. Colberg, Florida State University; Rendigs Fels, Vanderbilt University; R. A. Gordon, University of California; B. W. Lewis, Oberlin College; and E. T. Weiler, Purdue University. It has been requested to develop and to implement with all due speed a program of action and assistance, as indicated above, and to report periodically to the Association.

EXECUTIVE COMMITTEE  
March 6, 1964

## 1965 SLATE OF OFFICERS

A nominating committee consisting of Gottfried Haberler, chairman, Avery B. Cohan, Richard M. Cyert, G. A. Elliott, Marc Nerlove, and Nathaniel Wollman has submitted the following slate of nominees for 1965 officers of the American Economic Association.

*President-Elect:*

Fritz Machlup

*Vice-Presidents:*

Nicholas Georgescu-Roegen

Alexander Gerschenkron

Charles J. Hitch

W. Arthur Lewis

*Executive Committee:*

Moses Abramovitz

Neil H. Jacoby

Henry A. Latané

Robert H. Strotz

*Representative, Social Science Research Council:*

Karl A. Fox

The annual meeting of the Association will be held in Chicago, December 28-30, 1964, with headquarters at the Conrad Hilton Hotel.

---

SURPLUS CENSUS REPORTS AVAILABLE FOR 1947, 1954, AND 1955

The Bureau of the Census is planning to dispose of surplus copies of reports based on 1947 and 1954 Censuses of Manufactures, the 1954 Census of Mineral Industries, and the 1955 Annual Survey of Manufactures. A limited number of the following publications are available:

*1947 Census of Manufactures*

- Vol. I General Summary
  - II Statistics by Industry
  - III Statistics by States
  - Indexes of Production
  - Product Supplement

*1954 Census of Manufactures*

- Vol. I General Summary
  - II Part 1 Industry Statistics, General Summary and Major Groups 20 to 28
  - Part 2 Industry Statistics, General Summary and Major Groups 29 to 39
  - III Area Statistics

*1954 Census of Mineral Industries*

- Vol. I Summary and Industry Statistics
  - II Area Statistics

*Annual Survey of Manufactures*

Volume for 1955 only

Interested persons should write promptly to the Publications Distribution Section, Bureau of the Census, Washington, D.C., 20233, indicating the volumes they would like to receive. Requests will be filled as long as the supply lasts. Although no charge will

be made for these publications, it will be necessary for the recipient to pay shipping charges in some cases.

### NSF GRANTS FOR GRADUATE SCIENCE FACILITIES

For the past three years the National Science Foundation has provided matching grant money for the renovation or construction of graduate facilities. In October, 1963, it issued a new booklet NSF 63-48, *Grants for Graduate Science Facilities*, which describes its facilities programs. The programs have been somewhat broadened. These grants provide financial support for those portions of facilities (excluding classrooms) that are to be used for basic scientific research or for graduate training in the sciences. Such facilities may be used by faculty, staff, and by graduate or postdoctoral students. The institutions must provide, from nonfederal sources, matching funds equal to the amount provided by the Foundation. Funds, up to 15 per cent of the total requested for construction and fixed furnishings, may also be requested for movable and general-purpose laboratory apparatus.

While the behavioral sciences have participated in the Foundation's facilities programs since their inception, a separate Behavioral Sciences Facilities Program was created in the summer of 1963. During the past three years approximately 50 grants have been made for behavioral science facilities. These have ranged from \$2,350 to \$1,400,000. Often two or more departments or research units submit a common proposal.

Inquiries concerning the facilities programs should be addressed to the Division of Institutional Programs, National Science Foundation, Washington, D.C., 20550. Since there are no "closing dates," proposals may be submitted at any time.

### Announcements

The National Institute of Social and Behavioral Science, in collaboration with the Section on Social and Economic Sciences of the American Association for the Advancement of Science, will hold sessions for contributed papers at the annual meeting of the A.A.A.S. in Montreal, Canada, December 26-31, 1964.

Association members interested in presenting a paper at these sessions should forward titles and 300-word abstracts not later than September 1 to Donald P. Ray, Director, National Institute of Social and Behavioral Science, 863 Benjamin Franklin Station, Washington, D.C., 20044. Papers should be based on research current or recently completed by the author. Subjects may concern any aspect of national or international economic problems. Topics of a multidisciplinary nature are also of interest.

Selected papers of the sessions will be published by the National Institute. The American Economic Association is an affiliate member of the Section on Social and Economic Sciences of the A.A.A.S.

---

The University of Michigan announces the establishment of the W. S. Woytinsky Lectureship Award. One thousand dollars will be awarded biennially "for the best book, article or speech in the broad field of economics to educate public opinion or influence economic or social policy." Questions concerning this award may be addressed to Woytinsky Award Committee, Department of Economics, University of Michigan, Ann Arbor, Michigan.

---

The Sidney Siegel Memorial Fund Committee wishes to announce free copies of the following books:

Siegel and Fouraker: *Bargaining and Group Decision Making*

Fouraker and Siegel: *Bargaining Behavior*

Siegel, with Siegel and Andrews: *Choice, Strategy and Utility*

Messick and Brayfield, editors: *Decision and Choice: Contributions of Sidney Siegel*

are available to students, in the United States or abroad, having a scholarly interest or being engaged in research in the area of individual choice behavior and bargaining be-

havior. To obtain copies of these monographs, the student should ask his major professor to write to Preston Cutler, Center for Advanced Study in the Behavioral Sciences, at 202 Junipero Serra Boulevard, Stanford, California, stating the name and address of the student and specifying which book is desired. All such requests will be honored until the Sidney Siegel Memorial Fund has been depleted. Contributions to the fund have been made by Fellows of the Center for Advanced Study in the Behavioral Sciences of the classes of 1957-58 and 1961-62.

---

The New England Council announces its 1964 Publications Prize Program for the selection and publication of outstanding research of economic development relevant to New England. Dissertations and manuscripts dealing with the process of regional economic change in general and New England in particular are eligible. For more detailed information write to Mr. Rudolph W. Hardy, Director of Economic Research, The New England Council, 1032 Statler Office Building, Boston, Massachusetts, 02116.

#### *Deaths*

Paul Baran, professor of economics, Stanford University, March 26, 1964.

Richard C. Kao, research staff, The RAND Corporation, January 1964.

Ben F. Lemert, professor emeritus, Duke University, October 28, 1963.

Frederick C. Mills, professor emeritus of economics, Columbia University, February 9, 1964.

Leo Silverman, instructor, department of economics, New York University, February 1964.

#### *Retirements*

H. A. Logan, professor emeritus, University of Toronto.

#### *Visiting Foreign Scholars*

Keith Hancock, University of Adelaide, Australia: visiting professor of economics, Princeton University, academic year 1964-65.

Hans J. A. Kreyberg, Technical University, Trondheim, Norway: visiting professor, department of economics, University of Minnesota, academic year 1963-64.

#### *Promotions*

Arnold P. Ballantyne: associate professor of economics, U.S. Air Force Academy.

Vladimir N. Bandera: associate professor, economics department, Boston College.

Robert E. Barckley: professor of economics, San Diego State College.

Nicholas A. Beadles: associate professor of economics, University of Georgia.

Paul T. Bechtol: associate professor of economics, Colorado College.

Herbert Chesler: assistant professor of economics, University of Pittsburgh.

J. H. Dales: professor of economics, department of political economy, University of Toronto.

L. Aubrey Drewry, Jr.: associate professor of economics, University of Georgia.

H. C. Eastman: professor of economics, department of political economy, University of Toronto.

D. F. Forster: assistant professor of economics, department of political economy, University of Toronto.

J. H. Green: professor of economics, department of political economy, University of Toronto.

John P. Henderson: professor, department of economics, Michigan State University.

Marvin Jackson: assistant professor of economics, Arizona State University.

Subbiah Kannappan: associate professor, department of economics, Michigan State University.

Anne O. Krueger: associate professor of economics, University of Minnesota.

J. I. McDonald: assistant professor of economics, department of political economy, University of Toronto.

Francis M. McLaughlin: assistant professor, economics department, Boston College.

H. David Maloney: professor of economics, DePauw University.

John E. Metcalf: associate economist, First National City Bank, New York, December 17, 1963.

Howard W. Nicholas: professor, department of economics, Clark University.

Dennis O'Connor: assistant professor of economics, Arizona State University.

Lloyd D. Orr: assistant professor of economics, Indiana University, February 1964.

Abraham J. Siegel: professor of industrial relations, Massachusetts Institute of Technology.

George Slasor: assistant professor of economics, department of political economy, University of Toronto.

Marjorie S. Turner: professor of economics, San Diego State College.

Ray O. Werner: professor of economics, Colorado College.

J. W. L. Winder: associate professor of economics, department of political economy, University of Toronto.

### *Administrative Appointments*

Gordon Bivens: acting chairman, economics department, University of Wisconsin Extension Division.

Irving Brecher: director, Centre for Developing-Area Studies, McGill University.

Cono Casella: professor of economics and director, Arthur T. Roth Graduate School of Business Administration, C. W. Post College of Long Island University.

Kenneth J. Curran: dean, Colorado College.

Robert L. Dickens: assistant dean of arts and sciences, Duke University, July 1963.

Denis A. Flagg: chairman, department of economics, San Diego State College.

William C. Frederick: professor of business administration and dean, Graduate School of Business, University of Pittsburgh, March 1, 1964.

Clara H. Friedman: director of research, National Board of the Coat and Suit Industry.

Frank B. Gopen: president, Investors Guidance Corporation.

Paul M. Jones: chairman, department of economics and business administration, Colorado College.

R. E. Ludt: senior vice-president, Celanese Corporation of America.

Charles L. Quittmeyer: administrative director, department of economics, College of William and Mary.

Roy J. Sampson: associate professor of transportation and acting head, department of marketing, insurance and transportation, School of Business Administration, University of Oregon, spring term 1964 and academic year 1964-65.

Donald A. Schwartz, University of Wisconsin-Milwaukee: administrative assistant to the Mayor of Milwaukee.

Elroy J. Steele: head, economics department, University of Omaha, September 1, 1964.

Frank I. Stern: assistant director and acting director of market research, New York Central System.

John Turnbull: chairman, department of economics, University of Minnesota.

Roger C. Van Tassel: executive director, New England Economic Research Foundation.

Norman J. Wood: chairman, department of economics, University of Georgia.

James S. Worley: director, Graduate Program in Economic Development, Vanderbilt University, 1964-65.

John Parke Young, U.S. State Department: Central American Common Market, Guatemala.

### *Appointments*

James W. Adams: instructor, department of economics, University of Georgia.

Robert Baldwin: professor of economics, University of Wisconsin.

Robert Berney: assistant professor of economics, Arizona State University.

Raford Boddy: assistant professor, department of economics, State University of New York at Buffalo.

Nicholas G. Bohatiuk: associate professor of economics, Le Moyne College, Syracuse.

John H. Boyd: instructor in economics, University of Minnesota.

Raul M. Branco: assistant professor of economics, University of Texas.

Vernon M. Briggs: assistant professor, department of economics, University of Texas.

John A. Brittain, Vanderbilt University: senior research staff, Brookings Institution, June 1964.

Byron W. Brown: instructor, department of economics, Michigan State University.

John Burgess: assistant professor, department of economics, Goucher College.

Omer L. Carey: assistant professor of business administration, College of Economics and Business, Washington State University.

Robert M. Carlisle: technical staff, Systems Analysis and Evaluation, Aerospace Corporation.

Reynold C. Carlson, Vanderbilt University: Ford Foundation, Rio de Janeiro, Brazil.

N. K. Choudhry, State University of New York at Buffalo: assistant professor of economics, department of political economy, University of Toronto.

Charles H. Cline: instructor in economics, University of Minnesota.

Lee Cobb: associate professor, department of business statistics, University of Alabama.

Benjamin J. Cohen: assistant professor of economics, Princeton University.

Jacob Cohen, Bowling Green State University: professor of economics, University of Pittsburgh, fall 1964.

John Conlisk, Stanford University: assistant professor of economics, Rice University, September 1964.

Morris A. Copeland: Robert Julius Thorne professor of economics, Cornell University, spring term 1965.

John G. Cragg, Princeton University: assistant professor, department of economics, University of Chicago, academic year 1964-65.

L. S. Curtis: lecturer, economics department, Washington University.

Norman Daniel: lecturer in finance, University of Alabama.

Albert L. Danielsen, Duke University: assistant professor of economics, University of Georgia.

Richard B. DuBoff: assistant professor, Bryn Mawr College, September 1964.

Noel J. J. Farley: assistant professor, department of economics, Goucher College.

David Felix: professor, economics department, Washington University, September 1964.

Peter Frevert: assistant professor, department of economics, State University of New York at Buffalo.

Justin Fuller: instructor, department of economics, University of Georgia.

Sigfried Garbuny: associate professor, department of economics, Georgetown University.

Robert R. Gigliotti, Bureau of Labor Statistics: Naval Warfare Analysis Group, Center for Naval Analyses.

William Gillies: assistant professor, Bureau of Business Research, University of Nebraska.

Michael Godfrey: assistant professor of economics, Princeton University.

A. J. Goldenthal: transportation economist, Ford Motor Company, Dearborn, Michigan.

Kenneth Goldin: assistant professor, department of economics, State University of New York at Buffalo.

Herschel Ivan Grossman: assistant professor of economics, Brown University, September 1964.

Marshall M. Hall, University of Wisconsin: assistant professor, economics department, Washington University, September 1964.

E. Wannamaker Hardin, Jr.: instructor, department of economics, Duke University, second semester, 1963-64.

Mitchell Harwitz: associate professor, department of economics, State University of New York at Buffalo.

Edward Heiden: assistant professor of economics, University of Wisconsin.

Samuel Hollander, Princeton University: assistant professor of economics, department of political economy, University of Toronto.

Janet M. Hooks: assistant professor of economics, Eastern Illinois University.

Donald L. Huddle, Vanderbilt University: assistant professor of economics, Rice University, September 1964.

Saul H. Hymans: assistant professor, University of Michigan.

Clinton E. Jencks, University of California: assistant professor of economics, San Diego State College.

Marvin G. Julius: extension associate, department of economics and sociology, Iowa State University.

David Kamerschen: assistant professor, economics department, Washington University, September 1964.

Everett Kassalow: professor of economics, University of Wisconsin.

William M. Keane, University of Colorado: assistant professor, department of economics and business administration, Duke University, September 1964.

Allen Kelley: assistant professor of economics, University of Wisconsin.

George K. Keyt: instructor in economics, University of Minnesota.

Boyd Franklin King: instructor, department of economics, Georgetown University.

Melvin L. Kliman: instructor in economics, University of Minnesota.

Jan Kmenta: assistant professor of economics, University of Wisconsin.

Marian Krzyzaniak, Wayne State University: associate professor of economics, Rice University, September 1964.

Gerald M. Lage: instructor in economics, University of Minnesota.

Jerome R. LaPittus: assistant professor of economics, Cornell University, September 1964.

Arlyn Larson: assistant professor of economics, Arizona State University.

John Lindauer: assistant professor of economics, Occidental College.

Gail B. MacDonald: instructor in economics, University of Minnesota.

Douglas MacEachin: instructor in economics, Miami University, academic year 1964-65.

John L. McEntaffer: instructor, department of economics, Bowdoin College.

Stephen A. Marglin: assistant professor of economics, Massachusetts Institute of Technology.

James Melvin: instructor in economics, University of Minnesota.

Thomas V. Munzenreider: instructor in economics, University of Minnesota.

Edward Murphy: instructor, department of economics, Georgetown University.

Mohammed I. Nadiri: assistant professor, economics department, Northwestern University.

Thomas H. Naylor, Tulane University: assistant professor, department of economics, Duke University, second semester, 1963-64.

Mian Abdul Hameed Naz: senior economic analyst, Planning Commission, City of Baltimore, February 1964.

Douglas Needham: instructor in economics, Princeton University.

Cecile Jaffe Newburg, U.S. Employment Service: labor economist, Division of Research, U.S. Dept. of Labor.

Hugh O. Nourse: associate professor, department of economics, University of Illinois.

William H. Oakland: assistant professor of political economy, Johns Hopkins University.

William A. Paton: visiting professor of accounting, School of Business Administration, University of Oregon.

Harold L. Pazer: assistant professor of business administration, College of Economics and Business, Washington State University.

William Pollak: instructor in economics, Princeton University.

Frederick C. Raines: assistant professor, economics department, Washington University, September 1964.

Daniel P. Remington: lecturer in marketing, School of Business Administration, University of Oregon.

John C. Ritchie: AID in Medellin, Colombia, February 1964 to February 1966.

Donald M. Roberts, University of Illinois: economist, Ernst and Ernst.

Hugh Rose, University of Rochester: associate professor of economics, department of political economy, University of Toronto.

Sherwin Rosen: assistant professor of economics, University of Rochester.

Richard Rosenberg: instructor in economics, University of Minnesota.

Reid Ross: lecturer, economics department, Washington University.

William R. Russell, University of Wisconsin: assistant professor, department of economics, Michigan State University.

Richard Sander: instructor in economics, University of Minnesota.

Donald J. Schilling: assistant professor of economics, University of Missouri, fall 1964.

Barney Schwalberg: assistant professor of economics, University of Wisconsin.

Carl C. Schwan, Jr.: instructor in business administration, Vanderbilt University, 1964-65.

Karl Shell: assistant professor of economics, Massachusetts Institute of Technology.

Lawrence G. Smith, University of Chicago: assistant professor of economics, San Diego State College.

Kevin C. Sontheimer: instructor in economics, University of Minnesota.

Gary Sorenson: instructor in economics, Claremont Men's College.

Harold W. Stevenson: professor of finance, School of Business Administration, University of Minnesota, summer 1964.

Richard E. Suttor: research associate, department of economics and sociology, Iowa State University.

Overton H. Taylor, Harvard University: professor of economics, Vanderbilt University, 1964-65.

Hans B. Thorelli, University of Chicago: professor of business administration, Indiana University.

Richard H. Timberlake, Jr.: professor of finance, College of Business Administration, University of Georgia, January 1964.

Joseph Tryon, Georgetown University: National Planning Association.

Donald P. Tucker, Massachusetts Institute of Technology: assistant professor, department of economics, University of Chicago, academic year 1964-65.

A. Dale Tussing: assistant professor of economics, College of Economics and Business, Washington State University.

Yaroslav Vanek: associate professor of economics, Cornell University, September 1964.

Enrique R. Vignes: research associate, Iowa State University, Iowa-Peru development project.

Neil Wallace: lecturer in economics, University of Minnesota.

Finis Welch: assistant professor, department of economics, University of Chicago, academic year 1964-65.

Jerome Wells: assistant professor, department of economics and Center for Regional Economic Studies, University of Pittsburgh, fall 1964.

Charles Wilber: assistant professor, department of economics, The American University.

James Wilde: instructor in economics, Princeton University.

Bruce W. Wilkinson: assistant professor of economics, department of economics and political science, University of Saskatchewan.

Thomas David Williams: lecturer in economics, Northwestern University.

Harold F. Williamson, Jr., Yale University: instructor, department of economics, University of Illinois.

Charles Winston: lecturer, economics department, Washington University.

Arthur W. Wright: instructor in economics, Oberlin College, fall 1964.

### *Leaves for Special Appointments*

S. N. Afriat, Rice University: Cowles Foundation for Research in Economics, Yale University, first semester 1964-65.

Morton S. Baraty, Bryn Mawr College: Ibadan University, Nigeria, 1963-64.

Martin J. Beckmann, Brown University: Institutsdirektor, Institut für Ökonometrie und Unternehmensforschung der Universität Bonn, Germany, summer and first semester 1964-65.

Martin Bronfenbrenner, Carnegie Institute of Technology: visiting professor, Cornell University, summer 1964.

John A. Buttrick, University of Minnesota: Fulbright Grant, University of Tokyo, academic year 1963-64.

A. W. Currie, University of Toronto: advisor to the Ministry of Transport of Nigeria, Lagos, Nigeria, academic year 1963-64.

George Delehanty, Northwestern University: visiting professor, Massachusetts Institute of Technology, 1964-65.

Frank T. de Vyver, Duke University: Fulbright Lecturer, University of Western Australia, second semester 1963-64.

Alfred L. Edwards, Michigan State University: assistant deputy Secretary of Agriculture, December 1, 1963 to November 30, 1965.

Eugene Elander, Miami University: Dayton campus, Miami University-Ohio State University, academic year 1964-65.

Edward C. Ettin, Duke University: visiting professor, Board of Governors of the Federal Reserve System, Washington, D.C., academic year 1964-65.

Edward M. Foster, University of Minnesota: Chief of Party, University of Minnesota-Los Andes-AID project in Bogota, Colombia, 1963-64.

Peter Gregory, University of Minnesota: Cornell University-University of Chile program in industrial relations and labor economics, AID, 1963-64.

D. G. Hartle, University of Toronto: Director, Royal Commission on Canada's Taxation.

John C. Hause, University of Minnesota: Institute for Defense Analysis, 1963-64.

George H. Hildebrand, Cornell University: Massachusetts Institute of Technology, academic year 1964-65.

Dell Bush Johannesen, University of North Carolina: visiting associate professor of economics, University of Texas, second semester 1963-64.

David Kaun, University of Pittsburgh: Brookings Institution, 1964-65.

Anthony Y. Koo, Michigan State University: visiting professor of economics, University of Michigan, academic year 1964-65.

Francis Kutish, Iowa State University: marketing specialist with AID in El Salvador, November 1963 for two years.

Bert C. McCammon, Jr., Indiana University: visiting professor, University of Washington, second semester 1963-64.

Alexander Melamid, New York University: University of Lagos, Nigeria, spring semester 1964.

Raymond F. Mikesell, University of Oregon: visiting professor, Graduate Institute of International Studies, Geneva, and advisor, U.S. Delegation to the United Nations Trade and Development Conference in Geneva, spring term 1964.

Richard A. Miller, Wesleyan University: National Science Foundation fellow, Massachusetts Institute of Technology, 1964-65.

Sam A. Morgenstern, U.S. Employment Service: Government of Israel.

Leon Moses, Northwestern University: Ford Foundation Faculty Research Fellowship, 1964-65.

Nathan Reich, Hunter College: Fulbright lecturer, University of Frankfurt, Germany, February 1964.

Ray C. Roberts, Old Dominion College: visiting associate professor, department of economics and business administration, Duke University, academic year 1964-65.

A. E. Safarian, University of Saskatchewan: visiting professor of economics, department of political economy, University of Toronto, academic year 1963-64.

Geoffrey S. Shepherd, Iowa State University: Chief of Party, AID in Viet Nam, March 1964 for one year.

Larry A. Sjaastad, University of Minnesota: Chief of Mission, University of Chicago-Cuyo-AID project in Mendoza, Argentina, 1963-64.

Kenneth Strand, Oberlin College: OECD in Paris, 1964-65.

Hans B. Thorelli, Indiana University: professor of marketing, Institute pour l'Etude des Méthodes de Direction de l'Entreprise, Lausanne, academic year 1964-65.

William P. Yohe, Duke University: Fellow, Center for Advanced Study in the Behavioral Sciences, Stanford University, academic year 1964-65.

Edward Zabel, University of Rochester: Cowles Foundation, Yale University, September 1964 to September 1965.

### *Resignations*

Mark A. Alexander: University of Pittsburgh, January 1964.

A. James Boness: University of Pittsburgh, April 1964.

Edward C. Fei: University of Wisconsin.

L. Reed Tripp: University of Wisconsin.

Martha Van Hoesen Barnett: Goucher College.

## AGGREGATE PRODUCTION FUNCTIONS AND MEDIUM-RANGE GROWTH PROJECTIONS

*By* RICHARD R. NELSON\*

The conceptual basis for believing in the existence of a simple and stable relationship between a measure of aggregate inputs and a measure of aggregate output is uncertain at best. Yet an aggregate production function is a very convenient tool for theoretically exploring some of the determinants of economic growth, and it has served as a framework for some interesting empirical studies. Moreover, in an attempt to assess the growth prospects for an economy, to identify the variables that are likely to determine the growth rate, and to examine the policies affecting growth, the explicit or implicit use of an aggregate production function is almost indispensable.

In recent years economists have developed a variety of aggregate production functions. Several of these models are quite similar in basic conception but focus on different variables or make different assumptions about the interrelationships of the variables. Some represent amendments of earlier models. The different models yield somewhat dissimilar explanations of past growth and contingency forecasts with respect to future growth. The purpose of this paper is to try to place several of these models within a general framework so that their assumptions and implications can be compared and evaluated. First, the variables and relationships stressed by several different but related aggregate production models and the explanations they provide of the 1929-60 growth record of the United States will be examined. In the course of doing this a general production function will be developed which treats the different models as special cases. Then the analysis will turn to certain complementarity relationships between the variables that earlier formulations have tended to slight. As an application of some of the ideas, the concluding section will briefly examine a few of the quite different contingency forecasts provided by the different

\* The author is with The RAND Corporation. Much of the work which underlies this study was undertaken while he was on the staff of the Council of Economic Advisers. The author is indebted to M. Brown, W. Capron, C. Cooper, E. Denison, B. Massell, M. J. Peck, J. Schlesinger, and R. Solow for many useful suggestions.

models and other aspects of the problem of forecasting economic growth.<sup>1</sup>

Before the different models are examined, it will be useful to set out the basic growth record they have to explain. Between 1929 and 1960 real deflated GNP grew at an average annual rate of approximately 2.9 per cent. However, the rate of growth of output varied considerably over the period. From 1929 to 1947 (roughly the period of the depression to the start of postwar normalcy), real GNP grew at an average annual rate of 2.5 per cent—the average of a significantly slower growth rate during the depression, a tremendous surge of output during the war, and a postwar slowdown. From 1947 to 1960 the growth rate averaged 3.5 per cent a year—somewhat faster through the mid-fifties and somewhat slower from the mid-fifties to 1960.

Between 1929 and 1960 there was also considerable variation in the amount of economic slack as measured by unemployed labor and underutilized capital. Since production functions of the sort examined in this paper are designed to deal with secular factors and are not well suited to deal with the effects upon productivity of changing degrees of slack, it is dangerous to examine year-to-year changes in GNP. Therefore, we will be concerned with the average growth rates over various periods where the end points are roughly comparable in terms of the unemployment rates. To adjust further for the differences in degree of slack at the various terminal dates used, the Okun cyclical adjustments will be used and all data normalized to a 4 per cent unemployment rate [16]. Potential GNP for a year is defined as what GNP would have been had the unemployment rate been at 4.0 per cent of the labor force. Potential labor input is defined as man-hours that would have been worked had the unemployment rate been 4.0 per cent. The Okun adjustment to derive potential labor input from actual labor input tries to take account of cyclical effects in average hours worked per week and labor force participation rates, as well as percentage employed. The adjustment to derive potential GNP from actual GNP involves the labor-input adjustment and a productivity adjustment related to the unemployment rate. If the Okun equations are used to adjust for unemployment being somewhat higher in 1960 than in 1929, the average rate of growth of real potential GNP over the period was approximately 3.1 per cent; 2.5 per cent from 1929 to 1947, and 4.0 per cent from 1947 to 1960 with growth slowing down in the latter part of this subperiod.

Although the different models tend to stress different variables and relations, all of them are based on the relationship between growth of output and growth of labor input and capital input. Table 1 shows the

<sup>1</sup> This paper will focus on short- and medium-run growth. The long-run, steady-state properties of the models will not be examined. This is not a paper on the "Golden Age." But for an interesting comparison of the long-range implications of several models, see E. Phelps, [17].

average rate of growth of potential GNP, gross capital stock, and potential labor input measured in man-hours for selected subperiods.

Perhaps the most interesting aspects shown by Table 1 are, first, only a small absolute variation in the rate of growth of labor input; second, considerable variation in the rate of growth of the capital stock with variations in the rate of growth of GNP positively associated with variations in the rate of growth of the capital stock; third, potential GNP growing at a faster pace than either capital input or labor input in each subperiod;<sup>2</sup> and, fourth, a more rapid growth of potential output after World War II than before. Whereas the division of the 1929-60 record into the subperiods of Table 1 is relatively arbitrary, almost any division shows these four phenomena. These are the facts that an aggregate analysis of economic growth must explain.

TABLE 1—THE HISTORICAL RECORD<sup>a</sup>  
(percentage annual growth rates)

Year	Potential GNP	Potential man-hours	Gross capital stock
1929-60	3.1	.7	2.0
1929-47	2.5	.5	1.0
1947-60	4.0	.8	3.6
1947-54	4.4	.7	4.0
1954-60	3.5	.8	3.1

<sup>a</sup> The growth of potential output estimates is derived by using the Okun adjustments on the GNP series. The data for growth of potential man-hours are derived from the Knowles [13] series for actual man-hours, adjusted to get potential man-hours by the Okun equations. The capital stock series is from E. Denison [5]. Since producer's plant and equipment has grown at almost the same rate (in each subperiod) as total capital, I have not had to decide which concept is more relevant.

### I. *A Comparative Analysis of Aggregate Production Functions* *The Cobb-Douglas Model and Its Extensions*

The analysis of this section will be concerned with the Cobb-Douglas model and its extensions. The analysis could have been built around the more general constant elasticity of substitution model [2], but within a wide range which probably brackets the elasticity of substitution the conclusions are little different from those drawn from the simple Cobb-Douglas model. This fact, quite surprising to me at least, is proved in The RAND Memorandum from which this article is derived [15, ap-

<sup>2</sup> This statement does not hold true for earlier periods. During the 1909-29 period, potential GNP did not grow as rapidly as did the capital stock. Since much of Douglas' data [7] was for this period, this is one explanation of why he was able to get relatively good fits of Cobb-Douglas models without assuming any growth of total factor productivity. Kendrick [12] has called attention to this phenomenon. It is clear that growth of total factor productivity has been much greater since 1919 or 1929 than before.

pendix]. The analysis of this section also will be limited by the assumption that the effect of technical change is to shift the production function without altering its basic shape—that technical change is neutral. The reason for this limitation is that it is extremely difficult to measure the “nonneutrality” of technical change.<sup>3</sup> However, the effects of nonneutral technical change are examined in the preceding reference.

*The Basic Cobb-Douglas Model.* The basic Cobb-Douglas production function with constant returns to scale can be written:<sup>4</sup>

$$(1) \quad O_t = A_t L_t^b K_t^{1-b}$$

where  $O_t$  is potential GNP in year  $t$ ,  $L_t$  and  $K_t$  are potential labor input and capital input, respectively, in year  $t$ ,  $A_t$  is an index of total factor productivity, and  $b$  and  $1-b$  are the elasticities of output with respect to labor and capital, respectively. In pure competitive equilibrium and assuming a number of other stringent conditions, the shares of capital and labor will be indicators of these elasticities.

Taking logarithms, differentiating, and assuming  $b$  to be a constant (the basic Cobb-Douglas, neutral technological change assumption), the rate of growth of output is:

$$(2) \quad \Delta O/O = \Delta A/A + b(\Delta L/L) + (1-b)(\Delta K/K)$$

where  $\Delta O/O$  is the relative rate of growth of GNP;  $\Delta K/K$  and  $\Delta L/L$  are the relative rates of growth of capital and labor inputs; and  $\Delta A/A$  is the relative rate of growth of total factor productivity, or to put the matter more accurately, the part of the growth of output that cannot be explained by the growth of capital and labor using the simple Cobb-Douglas growth equation.<sup>5</sup> In a very real sense it is a measure of our ignorance.

Let us assume that the shares of labor and capital do provide an approximation to the output elasticity and roughly equal .75 and .25 over the period.<sup>6</sup> Further, assume that growth of man-hours and of gross capital stock are suitable measures of the growth of the services of these inputs.<sup>7</sup> Then  $\Delta A/A$  can be calculated as a residual,  $\Delta O/O - b(\Delta L/L) - (1-b)(\Delta K/K)$ , and for  $b = .75$  is presented in Table 2, column 1.

<sup>3</sup> But for one attempt, see [4].

<sup>4</sup> See Solow [25] for an example of the use of this kind of model, incorporating technological change.

<sup>5</sup> The relating of changes in GNP in one year to changes in the capital stock during that same year ignores problems of lags. However, since the analysis of this paper is concerned with average behavior of  $\Delta O/O$  and  $\Delta K/K$  over periods of several years, this problem is less serious.

<sup>6</sup> The sensitivity of the growth rate to different assumptions about output elasticities will be examined later. The  $b = .75$  assumption perhaps should be considered an upper bound.

<sup>7</sup> Obviously there are some serious problems in using capital stock as a measure of capital input. Vernon Smith's suggestion [22] that stock is the relevant concept is comforting but not

Notice what a large share of the average annual growth rate the unexplained residual is made to explain (approximately two-thirds in all of the subperiods).<sup>8</sup> And notice that, still assuming  $b$  to be approximately .75, the postwar acceleration of growth must be, in large part, explained by an increase (by more than one-third) in the rate of growth of total factor productivity. Similarly, the retardation since 1954 must be explained by a slackening-off (but not to the prewar rate) of growth of total factor productivity.<sup>9</sup> These conclusions, however, are strongly dependent upon the assumption that  $b = .75$ .

Table 1 showed, first, that throughout the period potential GNP grew faster than either input, but capital grew faster than did labor;

TABLE 2—GROWTH OF TOTAL FACTOR PRODUCTIVITY\*  
(percentage annual growth rates)

Year	$\Delta A/A; b = .75$	$\Delta A/A; b = .5$	$\Delta O/O$
1929-60	2.1	1.7	3.1
1929-47	1.9	1.7	2.5
1947-60	2.5	1.8	4.0
1947-54	2.9	2.1	4.4
1954-60	2.1	1.6	3.5

\* From Table 1 using equation (2).

second, that labor grew at a relatively constant rate; and, third, that the rate of growth of the capital stock varied considerably over the period, with simultaneous relatively rapid growth of both GNP and capital. Given these data, the greater the weight placed by the production function on the growth of capital—that is, the greater is  $(1 - b)$ —the less weight must be placed on the average rate of growth of total factor productivity in explaining average growth of GNP. (If the assumption of constant returns to scale is relaxed and the coefficients can add up to greater than one, the importance of  $\Delta A/A$  can be further reduced.)

completely convincing for this kind of analysis. Zvi Griliches, in an unpublished manuscript, has estimated that capital services have grown faster than gross stock by about half a percentage point a year.

<sup>8</sup> If Griliches is correct that capital services grew significantly faster than gross capital stock, then the unexplained residual is reduced somewhat, but it still is very large.

<sup>9</sup> Although almost any division of subperiods will show a postwar acceleration, it should be noted here that the selection of subperiods has influenced the interpretation of this phenomenon. Much of the increase in  $\Delta A/A$  over its pre-1947 average was concentrated in two short periods of time: 1948-50 and 1957-59 [5]. In other postwar years  $\Delta A/A$  was not significantly greater than its 1929-47 average. I do not know how this should be interpreted; in part, the explanation may lie in inadequate statistics. In any case, whether or not the increases in total factor productivity accounted for during these two periods are assumed to be, in fact, occurrences more evenly spread out in time, it is clear that  $\Delta A/A$  has, on the average, been higher since 1947 than before 1947 and probably has slowed down somewhat in recent years.

The low weight assigned to capital elasticity in the preceding calculations ( $1-b=.25$ ) resulted from the assumption (extraneous to the model) that factor shares are good estimates of factor elasticities. If this assumption is not adopted but rather  $b$  and  $\Delta A/A$  are obtained by regression, the estimated  $(1-b)$  is much larger—in the neighborhood of .5 or greater. And the average  $\Delta A/A$  for the period is smaller, as is shown in Table 2. More important, changes in  $\Delta A/A$  play a much smaller role in explaining changes in the growth rate over the subperiods, since the changes in  $\Delta K/K$  now “explain” a larger share of the concurrent changes in  $\Delta O/O$ .

However, this result carries no great economic insight. The variation in  $\Delta A/A$  calculated as a residual over the period represents the “errors” in a regression equation fitted for the entire period, and, if a regression is formally fitted,  $b$  will be calculated so as to minimize the variation of  $\Delta A/A$ . To put it another way, since  $\Delta L/L$  is (empirically) relatively constant, and since  $\Delta A/A$  is (by assumption of the regression) also a constant, the regression calculations will choose a  $(1-b)$  best suited to “explain” changes in  $\Delta O/O$  from changes in  $\Delta K/K$ . But if we have extraneous (to the model) information about  $b$ , the regression model must be constrained to take this information into account. If we continue to think strictly within the framework of the simple Cobb-Douglas model, the choice between the low  $(1-b)$ , and consequent large variation in  $\Delta A/A$ , explanation of past growth, and the high  $(1-b)$ , and consequent small variation of  $\Delta A/A$ , explanation depends on one’s judgment on, first, the extent to which factor shares provide good estimates of factor elasticities (which in turn depends on which of the wide number of theories of income shares one holds), and, second, whether it is likely that the rate of technical change has in fact increased in the postwar period.<sup>10</sup>

In any case, it is extremely important that  $\Delta A/A$  be explained. A growth theory that explains half of growth and much of the variation in growth by an unexplained residual (which is, after all, what “growth of total factor productivity” really is) is not much of a theory [6]. There are several different models that can be considered as providing amendments to the Cobb-Douglas model, which try to probe into the nature of  $\Delta A/A$ . One focuses on improvements in the quality of the capital stock. Another focuses on improvements in the quality of the labor force. By providing different descriptions of the determinants of  $\Delta A/A$ , these models further enrich the set of possible interpretations of the 1929–60 growth record.

<sup>10</sup> If it is not assumed that  $b$  was a constant over the period, but instead possibly varied from subperiod to subperiod, then the range of alternative explanations increases greatly. For such an analysis, see Brown and Popkin [4]. While this possibility is excluded by the assumptions of this section, the more general model developed in [15, appendix] does admit this possibility.

*Capital Quality and the Embodiment Effect.* One of the factors that has contributed to the growth of total factor productivity has been advances in technology which have improved the productivity of new capital goods. In his 1959 article, Robert Solow [23] suggested that the basic Cobb-Douglas model did not take account of the strong complementarity between technical change and investment. In his article, and in subsequent articles based on it [26], a distinction is made between "organizational" improvements which do not require new capital and "design" improvements which do. In contrast with the implicit assumption of the basic Cobb-Douglas model, Solow assumed that design improvements need to be embodied in new capital equipment. The effect of this need for "embodiment" is, as we shall see, to raise the sensitivity of the growth rate to changes in the rate of growth of capital.<sup>11</sup>

The Solow model can be written:

$$(3) \quad O_t = A'_t L_t^b J_t^{1-b}.$$

Although  $K$  in the basic Cobb-Douglas model is, in a sense, the number of machines (a proxy for the flow-of-machines services),  $J$  in a Solow model is a quality-weighted number of machines with new machines given greater weight than old machines, reflecting the newer technology embodied in them.  $A'_t$  is an index of economic efficiency, differentiated from  $A_t$  of equation (1) by the fact that  $A_t$  includes things that are incorporated in  $J_t$  as well as in  $A'_t$  of equation (3).<sup>12</sup>

The rate of growth is:

$$(4) \quad \Delta O/O = \Delta A'/A' + b(\Delta L/L) + (1-b)(\Delta J/J).$$

Assuming that advancing technology permits the quality of new machines to improve at  $\lambda_k$  per cent a year,  $J$  can be written:

$$(5) \quad J_t = \sum_0^t K_{v,t}(1 + \lambda_k)^v.$$

$K_{v,t}$  is the amount of capital built in year  $v$  (of vintage  $v$ ) which is still in use at time  $t$ .<sup>13</sup>

<sup>11</sup> It should be noted here again that the analysis of this paper relates for the short and medium run, not the long run, steady state, or "Golden Age."

<sup>12</sup> In a later formulation of his model, Solow separates plant from equipment in his  $J$  measure.

<sup>13</sup> It is important to note that  $K_{v,t}$  is gross capital of vintage  $v$  remaining at time  $t$ , and its measurement does not take into account any declines in value due to obsolescence.  $K_{v,t}$  is smaller than  $K_{v,v}$  if the physical productivity of machines declines through the years or if some machines are actually discarded. But the effect of obsolescence is not in the  $K_{v,t}$  measure. Let  $C_{v,t}$  be the measure of the value of capital of vintage  $v$  at year  $t$  which includes the effect of obsolescence. Then, if the productivity of capital improves at a rate  $\lambda_k$  a year,

$$C_{v,t} = K_{v,t}(1 + \lambda_k)^{-(t-v)},$$

or

$$K_{v,t} = C_{v,t}(1 + \lambda_k)^{t-v}.$$

To compare the growth implications of equations (2) and (4), it is useful to use the following approximation to equation (5):<sup>14</sup>

$$(5a) \quad J_t = B(1 + \lambda_k)^t K_t [1 + \lambda_k(\bar{a}_o - \bar{a}_t)].$$

Here  $\bar{a}_t$  and  $\bar{a}_o$  are the average ages of capital at times  $t$  and  $o$ , respectively.<sup>15</sup> This simplification involves a single moment of the age distribution of capital and replaces an equation involving the full distribution of vintages. Empirical tests suggest that equation (5a) is a very good approximation indeed.<sup>16</sup>

For small values of  $\lambda_k$  and  $\bar{a}_t$  not very different from  $\bar{a}_o$ ,  $\Delta J/J$  then can be approximated by:<sup>17</sup>

$$(6) \quad \Delta J/J = \Delta K/K + \lambda_k - \lambda_k \Delta \bar{a}.$$

$\Delta \bar{a}$  is the change in the average age of capital. Equation (6) makes a good deal of economic sense and could have been arrived at directly. The first two terms of equation (6) give the rate of growth of the quality-adjusted capital stock when the age distribution of the capital stock is not changing through time. The third term provides an adjustment when the age distribution is changing. A given age distribution determines a given difference between average quality and the quality of new capital. If each old machine were one year older, the difference between average quality and new quality would be larger by  $\lambda_k$ . More generally change in the gap between average quality and the quality of new equipment is approximately equal to  $-\lambda_k \Delta \bar{a}$ .

Using equation (6) in equation (4):

And, using equation (5),

$$J_t = \sum_0^t C_{vt}(1 + \lambda_k)^{t-v}(1 + \lambda_k)^v = (1 + \lambda_k)^t C_t,$$

and

$$\Delta J/J \approx \lambda_k + \Delta C_t/C_t.$$

Thus the Solow embodiment model reduces to the simple Cobb-Douglas if capital net of obsolescence is used in the equation.

$$^{14} (1) \quad J_t = (1 + \lambda)^{-\bar{a}_o}(1 + \lambda)^t \sum K_{vt}(1 + \lambda)^{\bar{a}_v - t}$$

$$(2) \quad J_t \approx B(\bar{a}_o)(1 + \lambda)^t K_t \sum K_{vt}/K_t(1 + \lambda v + \lambda \bar{a}_o - \lambda t)$$

where  $B(\bar{a}_o) = (1 + \lambda)^{-\bar{a}_o}$ .

$$(3) \quad J_t = B(1 + \lambda)^t K_t \left[ 1 + \lambda \bar{a}_o - \sum \frac{K_{vt}}{K_t} \lambda(t - v) \right]$$

$$(4) \quad J_t \approx B(1 + \lambda)^t K_t [1 + \lambda(\bar{a}_o - \bar{a}_t)]$$

<sup>15</sup> Knowles [13] also works with an "average age" model.

<sup>16</sup> Various series of  $J$  for different values of  $\lambda$  prepared by Richard Attiyeh were compared with series of  $J$  using the approximation formula. In all cases the series were almost identical.

<sup>17</sup> Thus  $1 + \lambda_k(\bar{a}_o - \bar{a}_t) \approx 1$ . The assumption that  $\bar{a}_t$  and  $\bar{a}_o$  do not differ significantly is appropriate for examining short-run changes.

$$(4a) \quad \Delta O/O = [\Delta A'/A' + (1-b)\lambda_k - (1-b)\lambda_k \Delta \bar{a}] \\ + b\Delta L/L + (1-b)\Delta K/K.$$

Save for the term  $-(1-b)\lambda_k \Delta \bar{a}$ , the growth equation for the embodied technical change model is similar to that for the simple Cobb-Douglas model.<sup>18</sup> If the average age of capital does not change,  $\Delta A'/A' + (1-b)\lambda_k$  is the rate of growth of total factor productivity, that is, the  $\Delta A/A$  of the original Cobb-Douglas model.  $(1-b)\lambda_k$  is the part that needs to be embodied in new capital, and  $\Delta A'/A'$  is the part that does not. The term involving changes in the average age, however, makes a great difference. Changes in  $\bar{a}$  reflect changes in the difference between the average technology in use and the best available technology. Given  $\Delta A'/A'$  and  $\lambda_k$ , the rate of growth of total factor productivity will be higher if the average age of capital is falling than if the average age

TABLE 3—CHANGES IN THE AVERAGE AGE OF CAPITAL\*

Year	$\bar{a}$ (average age)	Subperiod	Average $\Delta \bar{a}$ (average change in average age)
1929	16.5	1929-60	+ .006
1947	20.0	1929-47	+ .20
1954	18.0	1947-60	- .23
1960	17.0	1947-54	- .28
		1954-60	- .17

\* The data are from Knowles [13].

is constant or increasing. We shall continue to call the bracketed set of terms "growth of total factor productivity."

Table 3 presents the average annual change in the average age of capital for the relevant subperiods of the 1929-60 period.

Zvi Griliches has suggested that one of the objectives of growth theory should be to reduce the unexplained residual; one of the ways that he has tried to do this is to consider explicitly improvements in the quality of capital.<sup>19</sup> In a way this simply passes back the problem to another stage—we still have to explain why the quality of capital increased. But it does permit us to understand better what is going on.

Let us assume for the moment (the assumption will be modified later) that all of total-factor-productivity growth is the result of design tech-

<sup>18</sup> Recalling an earlier footnote, notice that, if the capital stock net of obsolescence is used rather than gross capital stock,  $J/J = \Delta C/C + \lambda_k$ . There is no term involving  $\Delta \bar{a}$  in the  $\Delta J/J$  equation and, if  $C$  rather than  $K$  is used in the  $\Delta O/O$  equation, there again is no term involving  $\Delta \bar{a}$ , since the average age of capital is caught in the net capital stock measure. In other words the "embodiment" effect is taken care of by the "net" capital measure.

<sup>19</sup> Z. Griliches [9] and also several unpublished manuscripts.

nical change that needs to be embodied, and hence all of the residual of the simple Cobb-Douglas model really is the result of the failure of the model to take into account improved capital quality. Then, for any value of  $b$ , in each of the subperiods  $(1-b)\lambda_k - (1-b)\lambda_k\Delta\bar{a}$  must, by definition, be equal to  $\Delta A/A$  as calculated from the simple Cobb-Douglas model. Thus, assuming all technical change to be embodied,  $(1-b)\lambda_k$  of the Solow model can be calculated from the relationship  $(1-b)\lambda_k = (\Delta A/A)/(1-\Delta\bar{a})$  where  $\Delta A/A$  is derived from equation (2) and was presented in Table 2. Estimates of  $(1-b)\lambda_k$  are presented in Table 4.

\* Data from Tables 2 and 3.

The implications of this extreme assumption are interesting. Notice that if all growth of total factor productivity were the result of technical change which needs to be embodied in new capital (improved quality of capital) and if  $(1-b)$  is assumed to be equal to .25 (capital's share of GNP), a considerable part of the variation in the growth rates during the subperiods is explained by different rates of growth of capital and labor and different trends in the average age of capital; thus less weight need be placed on variation in  $\lambda_k$ . These factors are sufficient to explain the postwar acceleration of growth, if not the slowdown in recent years. There is no need to assume that "technical change" was faster in the immediate postwar era than in the prewar era. In a way embodiment explains too much because, with the full-embodiment model, it is necessary to assume that since 1954 the rate of technological progress has fallen sharply below its 1929-54 rate. But in general, assuming  $(1-b) = .25$ , and assuming a constant rate of technological progress, differences in the rate of growth of total factor productivity during the subperiods are relatively well explained by a widening gap between best practice and average practice before 1947 (reflected in a growing average age of capital) and a narrowing gap in the postwar period (reflecting in a falling average age of capital).

In the Solow model, has a mysteriously changing average age of capital replaced a mysteriously changing rate of growth of technology as the primary factor explaining changes in the growth rate? Not at all. Changes in the trend of the average age of capital are explained very nicely by changes in the rate of growth of the capital stock.

Assuming exponential depreciation (exclusive of obsolescence) at a rate  $\delta$  a year, changes in the average age of capital can be approximated by the following expression:<sup>20</sup>

$$(7) \quad \Delta \bar{a} = 1 - (\Delta K/K + \delta)(\bar{a}_{t-1}).$$

Empirical checks suggest that equation (7) is a quite good approximation formula. Equation (7) makes good economic sense.  $\Delta K/K + \delta$  is the rate of gross capital formation. If gross capital formation is zero, at the end of a year all old capital will be one year older, and there will be no new capital, so  $\Delta \bar{a} = 1$ . At the end of a year  $\Delta K/K + \delta$  is the ratio of new capital to total capital. The effect of new investment on the average age of capital is greater, the greater new investment is relative to the total capital stock, and the greater the average age of that capital stock.

<sup>20</sup> Let  $K_{ij}$  be the amount of capital built at time  $i$  that is still remaining at time  $j$ . Then:

$$\bar{a}_t = \frac{K_{t-1,t} + 2K_{t-2,t} + 3K_{t-3,t} + \dots}{K_t}$$

$$\bar{a}_{t-1} = \frac{K_{t-2,t-1} + 2K_{t-3,t-1} + 3K_{t-4,t-1} + \dots}{K_{t-1}}.$$

But since

$$K_t - K_{t,t} = K_{t-1,t} + K_{t-2,t} + \dots$$

$$\bar{a}_t = \frac{K_{t-2,t} + 2K_{t-3,t} + 3K_{t-4,t} + \dots}{K_t} + \frac{K_t - K_{t,t}}{K_t}.$$

Assuming

$$K_{t-j,t} = (1 - \delta)K_{t-j,t-1}; \text{ and } K_t = (1 + \Delta K/K)K_{t-1}$$

$$\bar{a}_t = \frac{(1 - \delta)}{(1 + \Delta K/K)} \bar{a}_{t-1} + \frac{K_{t-1}(1 - \delta)}{K_{t-1}(1 + \Delta K/K)}$$

$$\bar{a}_t - \bar{a}_{t-1} = \frac{1 - \delta}{1 + \Delta K/K} - \frac{(\Delta K/K + \delta)\bar{a}_{t-1}}{1 + \Delta K/K}.$$

Thus for small  $\Delta K/K$  and  $\delta$ :

$$\Delta \bar{a} = 1 - (\Delta K/K + \delta)\bar{a}_{t-1}.$$

It might be noted that a more exact approximation is:

$$\Delta \bar{a} = 1 - (\Delta K/K + \delta)(\bar{a}_{t-1} + 1).$$

Using this equation for any  $\Delta K/K$  and  $\delta$ , it is possible to compute the long-run equilibrium average of capital:

$$\bar{a}_\infty = \frac{1}{\Delta K/K + \delta} - 1.$$

Thus, an increase in the rate of growth of capital would tend to increase the rate of reduction in the average age of capital (or reduce the rate of increase) or, in other words, in the medium run (if not in the very long run) [17] "embodiment" raises the sensitivity of the growth rate to the rate of growth of capital. What the simple Cobb-Douglas model misses is that the effect of capital growth on growth of potential *GNP* is determined not solely by  $(1-b)$ , but also by the rate at which "design improvements" are occurring and the gap between best practice and average practice. To put it another way, new investment not only leads to "more" capital—the magnitude of the effect determined by  $(1-b)$ —it leads to "more productive" capital—the magnitude of the effect determined by  $\lambda_k$  and  $\bar{a}_t$ .

Substituting equation (7) in equation (4a):

$$(4b) \quad \begin{aligned} \Delta O/O &= \Delta A'/A' + (1-b)\lambda_k \bar{a}_{t-1} \delta + b \Delta L/L \\ &+ (1-b)(1 + \lambda_k \bar{a}_{t-1}) \Delta K/K. \end{aligned}$$

Notice that the coefficient in front of  $\Delta K/K$  is no longer simply  $(1-b)$ . If  $(1-b)\lambda_k = .02$  and  $\bar{a}_t = 18$ , then  $(1-b)(1 + \lambda_k \bar{a}_{t-1}) = .59$ , more than double  $(1-b) = .25$ . The effect of embodiment, just as the effect of  $(1-b)$  larger than capital's share of national income, is to increase the sensitivity of the rate of growth of *GNP* to the rate of growth of the capital stock.<sup>21</sup>

To recapitulate, the simple Cobb-Douglas model (with constant weights) yields two possible interpretations of the 1929-60 growth record. If  $\Delta A/A$  is assumed to be constant, the growth record is explained by  $(1-b)$  significantly greater than .25. If, on the other hand,  $(1-b)$  is assumed to be approximately .25, changes in  $\Delta A/A$  account for a major share of the changes in  $\Delta K/K$ . Under this second interpretation, the correlation between  $\Delta A/A$  and  $\Delta K/K$  needs to be explained.

The Solow model provides one possible explanation.  $\Delta A/A$  is the result of technical change which needs to be embodied in new capital; growth of total factor productivity is really the result of improvement in the quality of new capital. Assuming  $(1-b) = .25$ , under this interpretation the variation in  $\Delta A/A$  needed to explain changes in  $\Delta O/O$  is quite well accounted for by variations in  $\Delta K/K$ , and there is little need to assume any dramatic change in the rate of growth of technological knowledge ( $\lambda_k$ ) over the period.

This is a very interesting result. However, unfortunately it is pushing the point a bit to assume that all growth of total factor productivity is

<sup>21</sup> Statistically, it would be quite easy to confuse the effect of embodiment with the effect of a large static output elasticity  $(1-b)$ . And, if the statistician did not assume that the production function were homogeneous of degree one, embodiment could easily be mistaken for a high capital elasticity plus economies of scale (the coefficients of labor and capital adding to greater than one).

the result of such "design changes." We know, for example, that education (which presumably does not need to be embodied in new capital) has played an important role. To the extent that  $\Delta A'/A'$  of equation (4) is not zero, then, assuming  $b$  to equal .75, changes in the average age of capital (caused by a varying rate of growth of the capital stock) are not sufficient of themselves to explain changes in the growth of total factor productivity among the subperiods. And the smaller  $\lambda_k$ , relative to  $\Delta A'/A'$ , the more the explanation of the acceleration of postwar growth must depend on either an increase in  $\lambda_k$  or  $\Delta A'/A'$ , or a  $(1-b)$  substantially in excess of the share of capital.

*Improved Labor Quality.* Solow has focused attention on improvements in the quality of the capital stock. Edward Denison, following Theodore Schultz's lead, has drawn attention to improvements in the quality of labor input [5] [21]. Without too much forcing, the Denison model can be interpreted as introducing an average labor quality variable into the new-style Solow model. Thus

$$(8) \quad O_t = A_t^* (L_t q_t)^b J_t^{1-b},$$

$$(8a) \quad O_t = A_t^* Q_t^b J_t^{1-b}.$$

Just as improvements in the quality of the capital stock are included in Solow's  $J$ , improvements in the quality of the labor force are included in Denison's  $Q = Lq$ . Just as  $A'$  was a narrower concept than  $A$ , so  $A^*$  does not include all that  $A'$  includes.<sup>22</sup> However, while it turns out that Solow's quality-of-capital measure can be nicely related to a single variable (the average age of capital can be related back to the rate of growth of the capital stock itself), as we shall see Denison's quality-of-labor measure is not so easily handled.

Defining  $\lambda_L = \Delta q/q$  so that  $\Delta Q/Q = \Delta L/L + \lambda_L$ , the basic Denison growth equation, modified to incorporate the results drawn from the Solow model, can be written as follows:

$$(9) \quad \begin{aligned} \Delta O/O = & \Delta A^*/A^* + b\lambda_L + (1-b)\lambda_k - (1-b)\lambda_k \Delta \bar{a} \\ & + b\Delta L/L + (1-b)\Delta K/K. \end{aligned}$$

In this formulation  $\Delta A^*/A^* + b\lambda_L + (1-b)\lambda_k - (1-b)\lambda_k \Delta \bar{a}$  is the rate of growth of total factor productivity,  $\Delta A/A$  of equation (2);  $\lambda_L$  is the rate of improvement in the average quality of the work force.  $\Delta A^*/A^*$  is improvements not directly "embodied" either in capital or labor (for example, improvements in the allocation of resources and better management practices).<sup>23</sup> Improvements that do not directly require em-

<sup>22</sup> For a somewhat different approach to the narrowing down of  $A$ , see Griliches [9].

<sup>23</sup> Since we are assuming that the static output elasticities add up to one, we are assuming away the possibilities of economies of scale as a source of growth of productivity. Of course, it is simple to relax this assumption.

bodiment in either capital or labor will be called "organizational."

It should be noted, however, that with a Cobb-Douglas type of function, improvements in the quality of *all* labor (or in average quality) can just as well be treated as disembodied change or as "organizational" change. While the breaking out of  $\lambda_L$  is an analytical convenience and permits us to understand the growth process better, as equation (9) is formulated, it is not correct to say that  $\lambda_L$  is productivity increase embodied in labor in the same sense that  $\lambda_k$  is productivity increase embodied in capital.

The reason that  $\lambda_k \Delta \bar{a}$  enters the expression although there is no comparable term involving  $\lambda_L$  is that  $\lambda_k$  is defined in terms of the quality of *new* capital, and  $\lambda_L$  is defined in terms of the average quality of all labor. Improvements in basic educational standards, which principally affect the new entrants to the work force, could be treated like  $\lambda_k$ , in which case there would be a term equivalent to changes in the average age of the work force in the growth equation. And, in fact, when Denison calculates the effect of education on growth, he proceeds in roughly this way.

Thus in the Denison formulation the term  $b\lambda_L$  has been added to the basic growth equation where  $\lambda_L$  is the rate of improvement in labor quality. Denison relates improvement in labor quality to three variables.  $\lambda_L^E$  is improvement in labor quality due to improvement in educational attainment. He assumes that 60 per cent of the income differential associated with greater education is attributable to education. To suggest the orders of magnitude involved, his calculations are roughly consistent with the rule of thumb; each additional year of education increases labor quality by approximately 6 per cent.<sup>24</sup> Denison calculates that, considering both the increase in the average number of years of schooling per person in the work force and the increase in the length of the school year, improved average educational attainment increased labor quality at roughly one per cent a year over the period.

Denison then considers the changing age-sex composition of the work force. He concludes that the rate of improvement in composition,  $\lambda_L^C$ , proceeded at an average annual rate of .1 per cent.

Finally, Denison argues that, as the average work week declines, labor productivity per man-hour increases but with diminishing returns. He assumes that between 1929 and 1947 more than half of the decline in the average work week was offset by consequent improvements in labor productivity, and between 1947 and 1960 the offset was approximately one-third. Over the entire 1929-60 period, the rate of improvement in

<sup>24</sup> Each additional year of education is associated with, roughly, a 10 per cent increase in average income. Denison assumes that roughly 60 per cent of this is the result of the increased education.

average labor quality due to declining average hours of work,  $\lambda_L^H$ , averaged .3 per cent a year according to Denison.

Table 5 shows Denison's estimates of  $\lambda_L^B$ ,  $\lambda_L^C$ , and  $\lambda_L^H$ . The table suggests that the rate of improvement in labor quality was roughly constant over the period. Assuming that  $b = .75$ ,  $b\lambda_L = 1.0$  per cent a year or improvements in labor quality account for roughly half of the average

annual growth of total factor productivity of 2.0 per cent a year experienced over the 1929-60 period.

While the details of Denison's calculations are extremely bothersome, no one would argue either that improved labor quality has not been important or that technological change which requires new capital in order to be effective is the full story of productivity growth.<sup>25</sup> It can be shown (see Table 6) that if Denison's estimate of the contribution of improved labor quality is roughly correct, and if the rest of the explanation of growth of total factor productivity is improved capital quality resulting from technical change that needs to be embodied, then, assuming  $(1-b) \approx .25$ , these two factors split the credit roughly fifty-fifty. Under this explanation, however, it is impossible to assume that both

<sup>25</sup> Note that if  $\Delta A/A \approx .02$  and  $1-b = .25$ , then, if all total-factor-productivity growth is technical change which needs to be embodied,  $\lambda_k \approx .084$  ( $b\lambda_k \approx .021$ ). It is interesting that Solow [26] never experiments with a  $\lambda_k$  this large. Naturally, therefore, his regressions yield a  $(1-b)$  much greater than .25.

$\lambda_L$  and  $\lambda_k$  have been constants. Taking Denison's estimate of a (constant)  $\lambda_L$ , the variation in  $(1-b)\lambda_k$  of Table 6 is significantly greater than the variation of  $(1-b)\lambda_k$  of Table 4, although less than the total variation in  $\Delta A/A$  during the several periods.

Even if Denison's estimates of the rate of improvement in labor quality are high (and his estimate of the contribution of the shortened average work week certainly is suspect), design technical progress which needs to be embodied in new capital (in the Solow sense) probably was less than half of total-factor-productivity growth. And the lower is  $\lambda_k$ , the less sensitive is the rate of growth of GNP to the rate of growth of the capital stock. Denison has suggested (both in his book [5] and in a recently published article [5a]) that even this low  $\lambda_k$  overstates the sensitivity of the growth rate of output to the growth rate of capital, since much of new technology requires only marginal modification or addition to equipment, not totally new plant and equipment.

The conclusion must be that the embodiment effect, as Solow describes it, cannot have been large enough so that changes in the rate of growth of capital fully explain the variations in the growth rate of potential GNP that the United States has experienced during the 1929-60 period.<sup>26</sup> If the shares of capital and labor are assumed to provide tolerably good measures of the static output elasticities, the evidence suggests that  $\Delta A^*/A^* + b\lambda_k + (1-b)\lambda_L$  increased sharply in the early post-war period and then declined somewhat after 1954. If we accept Denison's data, which suggest that  $\lambda_L$  has been relatively constant, the burden must fall on changing  $\lambda_k$  and  $\Delta A^*/A^*$ .

However, it is very interesting that  $\Delta K/K$  and growth of total factor productivity have been so highly correlated. Although the Solow type of embodiment cannot fully explain this correlation, perhaps other factors can.

## II. *The Cobb-Douglas Model in a More General Analysis of Economic Growth*

Solow's interaction effect describes one of the interactions among the variables of the Cobb-Douglas model, but there may be a number of other important relationships between the variables. They may be linked in the sense that changes in one determine the effect of changes

\* Somehow many economists have come to view the requirement that new technology be embodied in new capital as in some sense a happy phenomenon. The reason for this seems to lie in the greater sensitivity of the growth rate to the investment rate that embodiment implies. But surely, the less the requirements for new technology to be embodied in new capital, the less costly is faster growth. Of course it might be replied that if growth itself were an objective regardless of cost, and if it were easier to influence  $\Delta K/K$  than other variables that affect growth, then a strong embodiment provides a strong handle for policy. But surely this is a strange argument.

in another. Changes in one may stimulate changes in another or changes in certain underlying conditions not explicitly included in the model may have an effect on several of the variables of the model. This section will examine several obvious but important examples of these phenomena.

### *Sources of Interaction*

*Education, Technical Change, and Improved Allocation.* Perhaps the greatest theoretical difficulty with Denison's method of examining the contribution of various factors to economic growth is that he does not deal explicitly with the very strong complementarity among the factors. In particular, it is quite clear that the effects upon GNP of the three principal contributors to growth of total factor productivity—technological change, improved educational standards and levels, and improved allocative efficiency—should not be viewed as independent.

Educated people, principally scientists and engineers, are a critical input to the research and development process; thus the rate at which technological understanding is increased is strongly related to the number of educated people applied to that purpose. The relatively high salaries these people receive are a direct reflection of their contribution to advancing technology. Were scientists and engineers the only inputs to the technological change process, then, in the absence of market imperfections, their salaries actually would be a good measure of technological change. Surely it is a mistake to measure the contribution of technological change to economic growth after subtracting the higher incomes that R&D scientists and engineers receive. Yet this is, in effect, what Denison's method does.

Although (as Denison points out) this direct and obvious linkage between educational input and technological change may not be of major quantitative importance, one might seriously propose the hypothesis that the need for and the return to educated people generally, not just research and development personnel, are in large part functions of the desired and actual rate of technological change. Industries and firms that have large research and development staffs also tend to have a relatively high percentage of scientists, engineers, and other trained people in other functions—management, sales, production [10]. This is scarcely surprising. New technological developments need to be evaluated by people in management who can understand them and who can understand the nature of the market for them. Information about new products needs to be communicated from the firm that develops them to the potential market by salesmen who can describe the product and its uses and can answer questions. In the early stages of production before the techniques become routinized, highly trained people are re-

quired to deal with the problems that invariably arise. In the absence of technological change, economic decision-making could be more routine. Just as R&D is essentially problem-solving, requiring highly trained people, the development of a new product or technique creates problems that require expertise in the form of experience and training, as well as imagination, for their solution. The relatively high remuneration of people who can deal imaginatively with these problems, just as the high salaries of R&D scientists and engineers, is in part, perhaps in major part, the reflection of the importance of technological change in economic growth. Should the pace of technological change diminish, the returns to higher education probably would also.

Nor can the importance of shifting allocation of labor and capital be evaluated independently of consideration of the effects of technological change. The fact that technological change proceeds at often dramatically different rates in different industries is one of the principal sources of economic disequilibrium in allocation of labor and capital. When technological change is relatively rapid in an industry faced by an elastic demand curve, it tends to increase the optimum share of the nation's capital and labor resources that should be allocated to that industry. A subsequent shift of labor and capital into that industry would increase national income. When technological change proceeds relatively rapidly in an industry facing an inelastic demand curve, that industry's optimum share of the economy's resources tends to decline. A subsequent shift of labor and capital out of that industry to others would be reflected in rising value of production. Clearly it would be a mistake to estimate the importance of technological change to economic growth by treating these subsequent reallocations as if they would have raised the value of output as much as they did, in the absence of technological change. For it is the pace and inequality among sectors of technological change which, in large part, determine the gains society can obtain by shifting resources from one industry to another.

Finally, to close the circle, one of the important lessons we have learned from experience with depressed areas and industries and with training and retraining programs is that basic literacy is almost a prerequisite for both learning of a new job and learning to do a new job. If a high level of education is essential to create technological change, a basic education is essential to permit people to adjust to it, and for the economy to gain maximum benefit from it. At lower levels as well as at higher levels, the returns to education are strongly affected by the pace of technological change.

*New Plant and Equipment as a Source of Economic Flexibility.* The preceding discussion has attempted to show that the sources of growth of total factor productivity cannot be viewed as independent. Thus it

might be useful to look more broadly at the relationship between physical investment and growth of total factor productivity.

Solow has focused attention on the fact that often new capital is needed to embody new technology. Yet surely the advantage that new equipment has over old is not limited to a more up-to-date technology. As relative factor and product prices change, as demand and technology change, as the size of the market increases, new plant and equipment can be tailored to the changing economic situation. New plant and equipment, as well as education, plays a major role in providing the economy with flexibility.

As Johansen has suggested in his growth model, plant and equipment once built may be quite inflexible [11]. It is designed to work with a certain quantity of labor and to produce a certain quantity of output, as well as being designed around a certain technology.<sup>27</sup>

Denison and others have suggested that movement of labor from the farms to higher-productivity jobs has played a relatively important role in U.S. economic growth during the 1929-60 period. Massell has estimated that shifts of the relative allocation of capital and labor between industries account for approximately one quarter of total-factor-productivity growth in the postwar era [14]. As was noted earlier, these shifts in allocation, and the increase in the value of GNP resulting from those shifts, should not be considered independent of technological change. And it is clear that these shifts were at least partially dependent upon the creation of new capital. To the extent that old capital is inflexible, additional labor cannot be added to it without sharply diminishing returns. The productive movement of labor from one sector or industry to another is limited by the rate at which new plant is being built in the industry to which labor is moving. Thus both directly and indirectly, there is complementarity between the rate of growth of total factor productivity resulting from better allocating resources (labor and capital), and the rate of growth of the capital stock.<sup>28</sup> This is not embodiment in the Solow sense, but it has the same effect.

<sup>27</sup> If it were not for this inflexibility, we would not observe the phenomenon of obsolescence. If old equipment were flexible, if it could operate with widely varying quantities of labor and other variable inputs, then old paid-for capital equipment in good condition could be made competitive with new equipment simply by operating at very high capital-labor ratios (higher capital-labor ratios than for new equipment). But we observe that old equipment tends to operate at lower capital-labor ratios than new equipment; and as new and increasingly productive equipment comes into the market, the inability of older equipment to operate at higher capital-labor ratios, and thus to reduce variable unit costs, sooner or later makes that equipment obsolete even if it is in fine physical condition.

It also should be noted here that inflexibility of a Johansen sort may tend to make factor shares and output elasticities diverge [18].

<sup>28</sup> It is interesting that Massell's results suggest that shifting allocation of capital has been more important than shifting allocation of labor. If the analysis above is correct, it should be difficult to distinguish between the effects of the two; however, Massell's results tend to reinforce the belief that capital growth contributes to more efficient allocation.

The Johansen type of inflexibility also suggests that the extent to which the economy takes advantage of economies of scale is dependent upon new capital, not just more capital. To the extent that plant and equipment are indivisible, they must be built with a certain market size in mind. To take full advantage of increases in the size of the market, new plant and equipment must be better suited than existing plant for that larger-size market. Similarly, new plant and equipment must be built to take advantage of new opportunities for specialization.

The Johansen model therefore suggests that the complementarity between growth of total factor productivity and growth of the capital stock is more general than that suggested by the Solow model. In the Solow model new capital is needed to embody new technology. In the Johansen model new capital is needed to take maximum advantage of changing economic opportunities generally. An increase in the rate of growth of the capital stock should lead to an increase in the rate of growth of total factor productivity, not only by reducing the gap between average and best technology, but by creating a capital stock better suited to present demands, relative factor costs, and opportunities for economies of scale. The distance between the existing state of the economy and the production-possibility frontier which would exist in a world of perfectly flexible capital is strongly related to the rate of new investment.<sup>29</sup>

This point carries added significance when the uncertainties surrounding new technology are recognized. Embodiment, even in the strict Solow sense, is not a one-shot proposition. The early versions of a new product or process are likely to be quite primitive and plagued by unforeseen difficulties. Improvement and perfection is a sequential learning process, and the rate of learning is dependent not only upon the length of experience with a particular version of the technology but on the rate at which suggested improvements actually are tried out. To the extent that these improvements require embodiment, the rate of learning is strongly affected by the rate of new investment. This complementarity between learning and investment has been stressed by Arrow [1]. And to the extent that experience and experimentation in actual use are important aspects of the process of technological change, the Arrow effect implies that rapid rate of growth of capital not only keeps the technology in use close to the frontier but also helps to accelerate the rate at which the frontier advances.

It should be noted, however, that Denison's point with respect to the limited amount of new capital needed to embody new technology is also

<sup>29</sup> Perhaps it is this type of notion that Frankel [8] had in mind when he developed his aggregate production function in which an increase in the stock of capital increases the level of economic efficiency generally.

relevant to the more general complementarity relationships discussed above. Certainly not very much new capital is needed to take care of a moderate shift in labor allocation. Not very much new capital is needed to permit experimentation and experience with new techniques. It is therefore likely that, in the short run at least, the complementarity effects of new investment are subject to rather sharply diminishing returns. Yet there could still be a substantial amount of difference in effect between a very low rate of gross investment (such as we experienced during the 1930's) and a somewhat higher rate, such as the postwar average, if not between the very high rates of the early 1950's and the somewhat lower rates of the late 1950's.

*Positive Feedback of Incentives.* The complementarity between changes in the rate of capital growth and of total-factor-productivity growth also is the result of positive feedback of incentives. When the pace of design technical change increases, the profitability of new equipment relative to old increases, and an increase in investment is stimulated. Indeed, much of modern investment theory is hinged on the notion that investment booms are, in large part, the result of the development of new products and processes. Thus an increase in  $\lambda_k$  should stimulate an increase in  $\Delta K/K$ .

Schmookler's analysis suggests that the incentive mechanism also works the other way [20]. When the rate of investment is high, the potential market for inventions which require embodiment is high, thus an acceleration of the growth of the capital stock should stimulate an increase in  $\lambda_k$ . When Schmookler's hypothesis is linked with the Arrow hypothesis, incentive for technological advance is linked with opportunities for experimentation. This combined effect quite probably is very powerful.

*The Effect of Prolonged Economic Slack.* The causes for the correlation between growth of capital and growth of total factor productivity go deeper. Both almost certainly are depressed by prolonged economic slack of the sort experienced during the 1930's. It also is clear that both are stimulated when the economy comes out of a depression or recession. When jobs are plentiful, there is less pressure for protection from foreign competition, less incentive for featherbedding, less resistance to the adoption of new technology. It also is clear that the rate of growth of the capital stock tends to be higher when demand is pressing on capacity than when capacity is slack. While it is not inconceivable that the magnitude and design of the capital stock might be such that producers would be operating at preferred operating rates while unemployment is high, empirically it seems to be true that over the 1929-60 period, when unemployment has been high, capital has been operated at less than desired rates.

The effect of full employment on managerial incentives for innovation and on labor mobility is less clear.<sup>30</sup> However, although there is not enough evidence at present to predict whether the rate of capital formation and of total-factor-productivity growth would be greater in an economy that sustained a high level of employment or in one that fluctuated with moderate amplitude around a high level, given our present institutional and political structure, it seems probable that either of these possibilities would generate a faster average growth rate than would an economy with chronic high unemployment.<sup>31</sup>

It is reasonable to believe, then, that save for the World War II period and the Korean War period<sup>32</sup> stimulation for both capital growth and growth of total factor productivity should have tended to move (inversely) with the unemployment rate over the 1929-60 period. A glance at Tables 1 and 2 suggests that this, in fact, has been the case. It should be noted that these cyclical effects on growth of the capital stock and of productivity are additive to the effects of slack on growth of man-hours and productivity that Okun has analyzed.

### *Some Implications of Interaction*

The analysis of interaction suggests that it is misleading to assume that the various factors resulting in the growth of total factor productivity are independent, and to estimate the contribution of technological change by examining the residual after having estimated the contribution of education, shifting allocation of resources, and so on. It also is misleading to assume that the contributions of the various factors leading to growth of total factor productivity are independent of the rate of growth of the capital stock.

The growth rate of potential output has varied considerably over the period, principally the result of related and interdependent changes in the rate of growth of the capital stock, the rate of technical progress, and improvements in economic efficiency generally. All these factors tend to move together. They tend to be encouraged by strong aggregate demand, discouraged by economic slack. A change in one tends to increase the importance of the others.

This suggests that a simple regression model that tries to estimate

<sup>30</sup> The data are reasonably clear that movement off the farms and to urban areas is greater in periods of high over-all employment. But the effect of full employment on labor mobility in the nonagricultural sectors is less clear.

<sup>31</sup> It may be significant that Kendrick, in comparing productivity growth in different industries, finds that industries which experienced only mild cyclical fluctuations tended to have a faster rate of growth of productivity than industries which experienced severe cyclical fluctuations.

<sup>32</sup> During these periods investment was limited by policy, and perhaps demand was so strong that incentives for innovation and for productive shifting of labor were dulled.

$\Delta A/A$ , or  $\lambda_k$ ,  $\lambda_L$ ,  $\Delta A^*/A^*$ , and  $b$  for any period by relating  $\Delta O/O$  to  $\Delta K/K$  and  $\Delta L/L$  may miss the point. The variables of the model are not independent, and  $\lambda_k$  and  $\Delta A^*/A^*$  are undoubtedly not constants.

Assume that the conclusions above are roughly correct; that changes in  $\Delta O/O$  are the result of interdependent changes in  $\Delta K/K$ ,  $\lambda_k$ , and  $\Delta A^*/A^*$ , and that  $\Delta L/L$  has been relatively constant compared with the other variables. Because changes in capital growth have been associated with changes in output growth, a simple linear regression would tend to give a high weight to  $(1-b)$  in a model that does not include the embodiment effect. In a model that did not assume constant returns to scale, the effect of embodiment could be misinterpreted as economies of scale (the coefficients adding up to more than one) and a relatively high static capital elasticity.

But we know more about the process of economic growth than the factors and relationships treated formally by the aggregative growth models we use. For example, if we believe that factor shares tend to equal the elasticities of output with respect to the factors, we are not justified in estimating  $b$  and  $(1-b)$  from a simple regression. If we believe that various components of total-factor-productivity growth are affected by growth of capital directly, or by the same variables that influence capital growth, we are not justified in assuming them to be constants, nor are we justified in estimating these variables by regression, ignoring this interaction effect. If we believe that the returns to education are related to the pace of technological change, we are not free to treat  $\lambda_k$  and  $\lambda_L$  as independent.

In sum, the aggregative production function may be a useful part of the framework for studying economic growth. But it is a mistake to try to introduce into the production function variables such as average years of education without an explicit theory that shows *how* that variable should be entered. Further, it is a mistake to ignore what we know about economic processes from other kinds of analysis. Regressions of growth of GNP with respect to growth of capital and labor should be constrained by what little we know of the relationship between output elasticities and factor shares. To accomplish this and also to take account of the other interactions discussed in this section probably will require that the production function be imbedded explicitly or in a richer, more complete model of economic growth [3].

### III. *Medium-Range Growth Projections*

The preceding analysis has some rather interesting implications with respect to medium-range (say one decade) growth projections. While the range of possible forecasting models is very wide, in order to limit the discussion it will be convenient to focus the discussion upon a com-

parison of the growth projections for the 1960-70 period that Robert Solow has derived from his model, and the projections of Edward Denison. However, great liberties will be taken in interpreting both of these authors.

### *The General Framework*

As shown in Section II, the amended Cobb-Douglas model can be written in three equivalent ways:

$$(10a) \quad \Delta O/O = \Delta A/A + b\Delta L/L + (1-b)\Delta K/K$$

$$(10b) \quad \begin{aligned} \Delta O/O = [\Delta A^*/A^* + b\lambda_L + (1-b)\lambda_k - (1-b)\lambda_k \Delta a] \\ + b\Delta L/L + (1-b)\Delta K/K \end{aligned}$$

$$(10c) \quad \begin{aligned} \Delta O/O = [\Delta A^*/A^* + b\lambda_L + (1-b)\lambda_k \bar{a}_{t-1} \delta] + b\Delta L/L \\ + (1-b)(1 + \lambda_k \bar{a}_{t-1}) \Delta K/K \end{aligned}$$

These are the basic equations we shall use for comparing alternative growth projections. For some purposes one version is more convenient, for other purposes another version. Note that all three versions can be interpreted as relating growth of output to growth of labor, growth of capital, and growth of productivity of capital and labor. The difference between equation (10a) and the other two versions is that equation (10a) contains no explicit interaction relationship.

In this paper we are not particularly concerned with the difficult problem of projecting potential labor input since the production functions being examined shed no light on that topic. For this reason the projection of the Bureau of Labor Statistics for labor force growth of about 1.7 or 1.8 per cent a year over the 1960-70 period will be accepted without criticism, and, for want of a better hypothesis, it will be assumed that, abstracting from cyclical considerations, the average work week will decline at .5 or .6 per cent a year. Thus potential man-hours will be assumed to grow at 1.1 to 1.3 per cent a year. This rate of growth is more than half again greater than the growth of potential man-hours during the 1929-60 period. This is mainly the lagged result of the relatively high birth rates of the postwar era.

Note that if the unemployment rate decreases over the period, the growth of actual man-hours would exceed the growth of potential man-hours as a result of cyclical gains in the employment rate, in the length of the average work week, and in the rates of labor force participation. Likewise, growth of actual output would exceed the growth of potential output due both to the cyclical effect on growth of man-hours and to the cyclical effect on productivity. Although the analysis of this section will be of potential output and input, not actual output, it is important to note that if the unemployment rate is 4.0 per cent in 1970 (as com-

pared with nearly 6.0 per cent in 1960), and if the Okun adjustments are correct, the annual rate of growth of actual GNP will average .6 percentage points greater than the rate of growth of potential GNP. Thus if potential grows at 4.0 per cent, and full employment is achieved in 1970, actual GNP will have grown at 4.6 per cent a year over the decade. And this is aside from any effects that decreasing economic slack would have on the rate of growth of potential GNP.

Once a rate of growth of labor input is assumed, the task of growth projection using the extended Cobb-Douglas model breaks naturally into two parts. The first is projection of a likely range for the rate of

TABLE 7—THE POSTWAR AND LONGER-RUN GROWTH RECORD\*  
(percentage annual growth rates)

Period	$\Delta O/O$	$\Delta K/K$	$\Delta A/A; b = .75$	$\Delta A/A; b = .5$
1929-60	3.1	2.0	2.1	1.7
1947-60	4.0	3.6	2.5	1.8

\* Data from Tables 1 and 2.

TABLE 8—COMPARATIVE PROJECTIONS\*  
(percentage annual growth rates)

	$\Delta O/O; b = .75$		$\Delta O/O; b = .5$	
	$\Delta A/A$ 29-60	$\Delta A/A$ 47-60	$\Delta A/A$ 29-60	$\Delta A/A$ 47-60
$\Delta K/K$ 29-60	3.5	3.9	3.3	3.4
$\Delta K/K$ 47-60	3.9	4.3	4.1	4.2

\* Data from Tables 1 and 2.

growth of the capital stock. The second is projection of a likely range of growth of total factor productivity. However,  $\Delta A/A$  and  $\Delta K/K$  can not be assumed independent.

Let us use the 1929-60 experience as a guide to the range of possibilities. The relevant numbers from Tables 1 and 2 are reproduced in Table 7.

Assuming  $\Delta L/L = .012$ , let us examine how the projected potential GNP growth rate depends on whether the 1929-60 experience or the 1947-60 experience holds during the 1960's for  $\Delta K/K$  and  $\Delta A/A$  for  $b = .75$  and  $b = .5$ , respectively.

Table 8 expresses the heart of the growth-projection problem. It matters a good deal whether the 1960-70 experience with respect to both growth of total factor productivity and growth of the capital stock resembles the postwar experience or the longer-run average experience.

Despite the fact that the simple Cobb-Douglas model (with factor shares providing estimates of output elasticities) places a low weight on growth of capital, the difference between the postwar rate of capital growth and the long-run average rate is so great that the difference matters greatly. Even in the low-capital-weight model ( $1-b=.25$ ), the difference in the rate of growth of capital over the two comparison periods makes almost as great a difference in the growth projections for the 1960's as do differences in the rate of growth of total factor productivity. And in the model in which capital is heavily weighted ( $1-b=.50$ ), they make almost all the difference.

As was pointed out in Section II, a model with a high correlation between rate of growth of total factor productivity and the rate of growth of the capital stock, but with a low static output elasticity with respect to capital, tends to yield the same conclusions as a low correlation, high static output elasticity model. It is not surprising, therefore, that the principal diagonals of the two matrices of Table 8 are almost identical. Solow's "embodied" technical change growth model brings out this point clearly.

### *Growth Projections with Complete Embodiment*

As was shown in Section II, since embodiment results in a high correlation between rate of growth of capital and rate of growth of total factor productivity, the "embodied" technical change model is capable of explaining changes in the rate of growth of potential GNP over the 1929-60 period without recourse either to a postwar acceleration of technical change or to a static elasticity of output with respect to capital significantly in excess of the share of capital in national income.

At the polar extreme, then, if all total factor productivity growth were the result of embodied technical change, and  $(1-b)$  were .25, then  $(1-b)\lambda_k$  over the 1929-60 period must have been 2.0 per cent a year. With  $\Delta A^*/A^*=\lambda_1=0$ , equation (10c) can be written:

$$(11) \quad \Delta O/O = [(1-b)\lambda_k \bar{a}_{t-1} \delta] + b\Delta L/L + (1-b)(1+\lambda_k \bar{a}_{t-1})\Delta K/K.$$

With  $\bar{a}_{t-1}=17$  (the average age of capital in 1960),  $\delta=.035$ ,  $\Delta L/L=.012$ , and  $(1-b)\lambda_k=.02$ , the growth rate would be the following function of the rate of growth of the capital stock:<sup>33</sup>

$$(11a) \quad \Delta O/O = .022 + .59\Delta K/K \text{ [Projection with full embodiment].}$$

If  $\Delta K/K=.02$  (the 1929-60 average), then  $\Delta O/O=.034$ . If  $\Delta K/K=.036$  (the 1947-60 average), then  $\Delta O/O=.044$ .

<sup>33</sup> The constant term of equation (11a) is  $(1-b)\lambda_k \bar{a}_{t-1} \delta + b\Delta L/L$ . The coefficient before  $\Delta K/K$  is, of course,  $(1-b)(1+\lambda_k \bar{a}_{t-1})$ .

*Projections with Limited Embodiment*

Equations relating the growth rate of potential GNP to the rate of growth of the capital stock also can be derived for the totally "disembodied" technological change extreme (equation (10a)). Assuming  $b = .75$  and assuming  $\Delta A/A = .02$  or  $.0025$  (the 1929-60 and 1947-60 rates respectively):

$$(12) \quad \Delta O/O = (.029) + .25\Delta K/K \text{ [Projection with no embodiment].}$$

$$(.034)$$

The values of  $\Delta O/O$  for  $\Delta K/K = .02$  and  $.036$ , for  $\Delta A/A = .02$  and  $.025$ , were given in Table 1.<sup>34</sup> Notice that the "embodied technical change projection" is more than twice as sensitive to the rate of growth of the capital stock as the more conventional model. Notice also that if equation (12) is used, the growth projector is forced to decide what rate of growth of total factor productivity to assume, for the experience of the 1929-60 period does not provide a unique answer.

This certainly is so for Denison. According to his model,  $\Delta A/A$  varied considerably over the period. Indeed both  $\lambda_k$  and  $\Delta A^*/A^*$  varied. Denison must make a choice here. The choice he actually makes is guided by several considerations.

Denison's analysis suggests several reasons why the rate of growth of total factor productivity should be less rapid during the 1960's than during the 1947-60 period. Increases in productivity resulting from declines in the work week should be much less important. There should be a decline in the rate of growth of average school years per worker. Productivity advance resulting from economies of scale should be smaller.

But, even assuming that this analysis is correct, and that the effect of the declining work week and of increasing educational standards will be weaker during the 1960's than in earlier decades, Denison still has some freedom left if he recognizes the fact that his "residual" was greater in the postwar era than in the prewar era. It is interesting that Denison ends up projecting a rate of technical change faster than the 1929-60 average, but significantly smaller than the 1947-60 average.<sup>35</sup> And, since he projects a decline in the effect of variables that contribute to growth of total factor productivity, he ends up actually projecting a slightly smaller rate of growth of total factor productivity during the

<sup>34</sup> The two constants of equation (12) result from the two different assumptions about  $\Delta A/A$ . The constants are  $\Delta A/A + b\Delta L/L$ .

<sup>35</sup> It should be noted that my use of 1947 as a dividing line between the postwar and earlier periods is critical here. Although Denison's projected rate of technological change is less than the 1947-60 average, it is roughly equal to the 1954-60 average rate, and to the 1950-60 average rate.

1960-70 period than during the 1929-60 period, not just than during the 1947-60 period.<sup>36</sup>

Denison's "best guess" projection is for a 3.3 per cent annual growth of potential GNP, with a growth of the capital stock of 2.5 per cent a year. Taking great liberties with Denison's formulation, assuming that  $(1-b)\lambda_k = .005$  and that all of  $\lambda_k$  needs to be embodied (which Denison correctly would deny), the basic Denison growth equation can be written:<sup>37</sup>

$$(13) \quad \Delta O/O = .025 + .33\Delta K/K \text{ [Denison, with full embodiment of } \lambda_k].$$

This yields a 3.3 per cent growth rate of  $\Delta K/K = .025$ . If  $\Delta K/K = .036$ , as it has averaged since 1947,  $\Delta O/O = .036$ .

But the growth-projection equation that Denison finally reaches is far less important than the analysis on which he bases his projection. The assumptions of interest are, first, that several of the factors contributing to growth of total factor productivity will be less important during the 1960's than earlier and, second, that embodiment is quite unimportant.

Denison undoubtedly is correct in assigning a smaller weight to  $\lambda_k$  than does the pure embodied technical change model. However, due to the strong links between education and technical change, his attempt to treat the effects of technical change as a residual undoubtedly leads to an understatement of the importance of technical change. He also undoubtedly is correct in arguing that often technological change requires only a small amount of new capital. But if the analysis of Section II is correct, he probably also has underestimated the importance of other, if less direct, connections between growth of capital and growth of total factor productivity. (Of course these are not treated by the formal embodiment model either.) And, although he may be right that the longer-run experience of growth of total factor productivity is a better prediction for the 1960's than the postwar experience, the point is surely open to question. Thus his estimates both of the constant and the capital growth sensitivity terms may well be low.

### *The Major Uncertainties*

While other projection models certainly could provide higher or lower forecasts, the comparison of the Solow and Denison projections suggests the range of uncertainty with respect to the medium-range

<sup>36</sup> This point of course is not dependent upon choice of subperiods.

<sup>37</sup> The constant in equation (13) is derived from Denison's projection of  $\lambda_L$  and  $\Delta A^*/A^*$  on the assumptions that  $b = .75$  (slightly smaller than Denison's assumption) and that  $\Delta L/L = .012$ . The coefficient before  $\Delta K/K$  is derived from the assumption that  $(1-b)\lambda_k = .005$ .  $\lambda_k$  and  $\Delta A^*/A^*$  were adjusted to add up to be consistent with Denison's projection for technological change plus changes in efficiency and economies of scale.

growth prospects of the U. S. economy and helps to identify the principal causes of the uncertainty.

To the extent that the experience of the 1929-60 period can shed light on the prospects for the future, during the 1960 period growth of potential GNP is likely to be somewhere between an annual rate of 3.2 per cent and 4.3 per cent. The high end of the range will be achieved if the rates of growth of the capital stock and of total factor productivity are at the postwar rate, the lower end if they are at the longer-run average rate.

Much of the uncertainty, therefore, relates to the interpretation of the acceleration of growth of capital and of total factor productivity in the postwar period. One interpretation is that the postwar spurt essentially represents a making up of ground lost during the Great Depression, that the slowdown during the past several years shows that the "making up" has been completed, and that the 1929-60 average represents an average of below-normal growth and above-normal growth. According to this interpretation we should not expect growth of the capital stock or of total factor productivity during the 1960-70 period to differ greatly from the 1929-60 average rates, and the recent slowdown suggests that to project the 1947-60 rates would be unrealistically optimistic.

Another interpretation is that the 1929-60 average is much too heavily influenced by the depression decade of the 1930's. While it probably is true that the very rapid rate of growth of capital and of total factor productivity during the 1947-54 period was, in large part, a make-up phenomenon, this cannot be said of the post-1954 period. It should be recalled that the rate of growth of the capital stock, since 1954, has been significantly greater than the 1929-60 average and, after adjusting for changing degrees of slack, the same is true of growth of total factor productivity. Further, it is quite clear that the average rate of growth of the capital stock since 1954 has been less than it would have been had fiscal and monetary policy been more effective in keeping aggregate demand pressing on aggregate potential. Growth of total factor productivity undoubtedly also has been depressed by economic slack.

Thus, according to this interpretation, the 1954-60 record (even more the 1929-60 record) significantly understates the growth of the capital stock and the growth of total factor productivity we may expect in an economy where aggregate demand is not permitted to lag significantly behind growth of economic potential.

Further, according to the more optimistic interpretation, the postwar increase in the rate of R&D spending has not been without effect. The latent rate of technical change—the rate at which productivity could

be increased as a result of new technical knowledge were there sufficient demand to spur innovation and reduce resistance, and sufficient investment to embody the new technology and to permit high labor mobility—probably has been greater in the postwar era than before. Even with the economic sluggishness of the past five years, which certainly has made innovation more difficult, the rate of growth of potential total factor productivity has exceeded its long-run average.

From analysis of the Solow and Denison projections it is clear that this difference in interpretation lies at the root of the differences in the growth projections. Perhaps looking at the experience of the economy over a longer period of time than 1929–60 can shed some light on which interpretation is likely to be more nearly correct. Between 1909 and 1960 the rate of growth of the capital stock averaged approximately 2.5 per cent a year, and between 1909 and 1929 the average annual rate of growth of the capital stock was approximately 3.0 per cent. This suggests that the 1929–60 capital growth experience probably was heavily affected by the depression years. And to the extent that growth of capital and growth of total factor productivity are correlated, this suggests that the 1929–60 experience for  $\Delta A/A$  also was heavily affected by the depression.

The experience of the past few years also suggests that since the war there has been a change and that it would be a mistake to extrapolate the longer run 1929–60 experience into the future. From 1959–62, potential GNP has grown at an annual rate of greater than 3.5 per cent. This is faster than the rate that Denison projects for the future. And yet, from 1959–62 the growth of labor input was significantly less than we can expect during the middle and late 1960's, and, as a result of persistent economic slack, the capital stock grew at an annual rate of only about 2.0 per cent. If we have in fact achieved an annual growth potential of approximately 3.5 per cent under these conditions, we certainly should do better as the rate of growth of the labor force increases, provided we can achieve and maintain adequate aggregate demand.

Although Solow's model undoubtedly overstates the correlation between growth of capital and growth of total factor productivity, Denison's model undoubtedly understates it. It is likely that during the 1960's the rate of growth of the capital stock and of total factor productivity will both be near the high postwar rates or neither will be. If this is correct, and if it also is correct that one of the major reasons for the postwar acceleration has been the absence of deep recession and (save for the past several years) prolonged slack, our growth record during the 1960's may be more dependent on an ability to reduce economic slack than on any other measure. We shall have full employment and rapid growth of potential GNP together or we shall have neither.

## MANUFACTURING INVESTMENT, EXCESS CAPACITY, AND THE RATE OF GROWTH OF OUTPUT

By ALICE BOURNEUF\*

Since the mid-fifties the United States has operated at less than full utilization of the labor force and plant capacity, even at the peaks of mild output fluctuations. A higher rate of growth of investment would have led to higher total output, assuming conventional multiplier effects. Another relationship may exist between the growth of output and investment in response to it. Would a higher rate of growth of output lead to correspondingly larger investment? If output fluctuated less, would investment be more stable, or higher? This study aims to throw some light on these questions. It analyzes manufacturing investment in the United States since 1950. Linear regression equations indicate close relationships between investment, excess capacity, and output changes, both in total manufacturing and in most of the industries analyzed. These equations can be used to obtain tentative answers to the above questions, assuming the relationships found are not themselves altered by changed conditions of output growth.

To analyze the effects of output changes on investment is to test some form of the acceleration principle. In its simplest mechanical form, the accelerator has failed to explain short-period changes in investment. A more flexible form of the accelerator is used in this study; investment is assumed to be negatively related to the difference between capacity output and actual output, positively related to total capacity, and positively related to the change in output. The acceleration principle cannot provide a complete explanation of investment, but it may explain a substantial part of it. Edwin Kuh emphasized recently that real and financial factors must be considered complementary [4, pp. 260-68] and suggested that accelerator-type forces may be more important in periods of pressure on capacity. This paper tests the accelerator in a period during most of which there was little or no pressure on capacity.

\*The author is professor of economics at Boston College. She is indebted to the Ford Foundation for the 1962-63 Faculty Research Fellowship which made this study possible, to Robert Solow for patient advice during that year, to Richard Caves for helpful suggestions, to Frank de Leeuw for invaluable critical comments and assistance, to the Economics Department at M.I.T. and the M.I.T. Computation Center for computer facilities, and to Boston College for financial assistance in the final stages.

### *I. Data Analyzed*

The choice of investment and output data was dictated by the desire to analyze individual industries. Investment data are the U. S. Commerce Department and Securities and Exchange Commission expenditures on new plant and equipment, converted to 1954 constant prices by using the Commerce Department's index of the prices paid by private purchasers of plant and equipment [13] [14]. Federal Reserve production indices were found for 13 industries for which investment data are available [9] [10]. The output indices were converted to 1954 value added by manufacture dollars by multiplying the ratio of the output index in any year to the 1954 index by the 1954 value added by manufacture.<sup>1</sup>

Measures of output capacity were used instead of estimates of the value of capital stock. It seemed worth while to experiment with the industry-capacity indexes compiled by McGraw-Hill and the total manufacturing-capacity indexes of McGraw-Hill and Frank de Leeuw. Capital stock estimates based on book-value data would have required much more extensive statistical work and raised difficult problems of valuation and depreciation.<sup>2</sup>

Measures of capacity also raise problems. An ideal measure might be capacity under normal operations, an engineering concept, or capacity at minimum average cost, or below some level of marginal cost, accounting concepts.<sup>3</sup> The capacity indexes used in this study are not ideal in either sense; they probably are closer to the engineering concept. McGraw-Hill indexes are calculated from capacity as individual manufacturers see fit to report it, and these manufacturers report preferred operating rates at 90 to 100 per cent of capacity. The de Leeuw index, which is based on three separate series, attempts to minimize bias and errors. The series are the McGraw-Hill capacity index, one of the new gross capital stock estimates of the Department of Commerce [3],

<sup>1</sup> The Census value-added totals were adjusted as far as possible to the coverage of the production indices, and the production indices to the coverage of the investment data. But the investment data are on a company basis, and the Census and Federal Reserve data on an establishment basis. Investment estimates include large expenditures for nonmanufacturing establishments, especially in primary metals and petroleum. For the source of the investment data see [13] and [14], of the production data see [9] and [10].

<sup>2</sup> Capital stock estimates for selected years for many industries have been compiled by the National Industrial Conference Board, see [1] and [2]. The capacity indexes of McGraw-Hill are in [11], of de Leeuw in [6] in the form of quarterly operating rates. End-of-year capacity indexes were furnished the author by de Leeuw.

<sup>3</sup> See [5] [6] and [7] for a discussion of problems of capacity measurement, and [6] for an explanation of the construction of de Leeuw's index. The de Leeuw index rises 1 per cent more per year than the Commerce series, and  $1\frac{1}{2}$  per cent less per year than the McGraw-Hill index, which in fact rises at the rate of the Commerce series for equipment only at Bulletin F lives.

and an index based on output data and on operating rates reported to McGraw-Hill.

The capacity indexes were converted into capacity output in billions of 1954 value-added dollars. The year 1955 was used as a base, since operating rates reported at the end of both 1954 and 1955 were close to capacity. Calculations of total output capacity based on operating rates and output for 1955 were, therefore, likely to be less subject to error than similar calculations for years of low operating rates. Capacity for the year 1955 was calculated by multiplying the 1955 output, in 1954 value-added dollars, by the reciprocal of the average of the two end-of-year operating rates.

## II. *Investment Equations*

A great many equations were fitted to the data since 1950.<sup>4</sup> The best results were obtained from the following equation, in which  $I$  is investment,  $C$  capacity,  $Y$  output, and  $C_{bt}$  is capacity at the beginning of the year  $t$  as distinct from  $C_t$ , which is average capacity for the year.

$$(1) \quad I_t = a(C_{t-1} - Y_{t-1}) + bC_{bt} + c \Delta Y_t + k.$$

The excess-capacity variable should have a negative effect on investment;  $C_{bt}$  is meant to catch replacement investment; and  $\Delta Y_t$  should have a positive effect on investment.

The equations fitted for total manufacturing and for most of the individual industries tested are reasonably good fits. The fact that many of the equations for individual industries are satisfactory suggests that the equation for total manufacturing has a sound basis in the behavior of individual industries.<sup>5</sup> The equations met one test of their estimating ability fairly well. Equations fitted to 1950-61 data were used to estimate 1962 investment. For total manufacturing and for nine of the 13 industries, the differences between the estimates and

<sup>4</sup>All of the equations tested were variations on the flexible accelerator theme. Equations fitted to total output, total capacity, and changes in output gave poor results, as did equations using the same variables in ratio form to avoid collinearity. Lagged changes in output did not help. When a direct measure of excess capacity looked promising, several experiments were made with lagged output changes, and with some variable to explain the important steady amount of replacement investment.

<sup>5</sup>The use of  $\Delta Y_t$  may be questioned on the ground that it may reflect the investment change rather than vice versa. The author believes this is not serious. Experiments with a change in GNP term instead of the change-in-output term produced very poor results. The simple correlation of changes in manufacturing output and changes in GNP is close, but the standard error of estimate of the regression equation equals about one-fourth of the average change in GNP. Changes in government expenditures and in residential construction have been calling the tune for changes in GNP. In any case the problem cannot be considered serious for the individual industry equations.

TABLE 1—COMPARISON OF ESTIMATED AND ACTUAL INVESTMENT FOR 1962 AND 1963  
(in billions of 1954 dollars)

	Estimated from Equation	Actual Total	Difference: Estimated minus Actual	Standard Error of Estimate of Equation	Ratio of Difference to Standard Error of Estimate
<b>PART A: TOTAL MANUFACTURING</b>					
Equations from 1950-61 data					
McGraw-Hill 1962	12.39	11.83	.56	.727	.77
de Leeuw 1962	12.21	11.83	.38	.639	.59

actual investment were less than, or close to, one standard error of estimate of the relevant equation; the differences in the other four industries were less than two standard errors (see Table 1). Provisional estimates for total manufacturing for 1963 were not so successful, even when equations were fitted to 1950-62 data.

The equations based on the de Leeuw index of total manufacturing capacity perform better than those based on the McGraw-Hill index. The de Leeuw equations are slightly better fits than the McGraw-Hill equations (see Table 2). In all of the total manufacturing equations the coefficients are significant at the .05 level and have appropriate signs. The correlation coefficients are about as high as can be expected with such a simple model. The standard errors of estimate of the de Leeuw equations are smaller than those of the McGraw-Hill equations, but the latter are well below 10 per cent of average investment.

### III. *Capacity Equations*

An analysis of the effect of output changes on investment must consider not only the direct effect of output changes on investment but also the indirect effect of output changes on excess capacity, and, through excess capacity, on investment. Furthermore, investment, as affected by output changes, then increases capacity, excess capacity, and replacement needs, and, therefore, in turn affects investment in future years. To analyze the full influence of output changes on investment over time an equation is needed to estimate the effects of investment on total capacity or on changes in capacity. A complete explanation of capacity would require many variables. With only 12 observations only simple equations could be tested, relating changes in capacity to investment this year or last year, or to last year's change in capacity. The equations relating this year's changes in capacity to this year's investment gave tolerably good results; to simplify the later analysis and computations, the equation was put in terms of total capacity at the beginning of successive years, as follows:

$$(2) \quad C_{bt} = a I_{t-1} + b C_{bt-1} + k.$$

The capacity equations for total manufacturing based on the de Leeuw index are fairly satisfactory (see Table 2), but those based on the McGraw-Hill index are less so. In the McGraw-Hill equations the coefficients of the  $I_{t-1}$  term are not significant at the .05 level. The correlation coefficients are very high, mainly because of the high degree of autocorrelation in the capacity series. The standard errors of estimate of the equations are tolerable, as they amount to about 15 per cent of the average change in capacity.

#### IV. *Investment and Capacity over Time*

An incomplete linear model of the behavior of investment and capacity over time may be obtained by combining equations (1) and (2) into a second-order difference equation in capacity and then assuming various output growth rates. Each of the four possible combinations of investment and capacity equations has roots which are positive and less than one. Assuming an exponential output growth rate, investment and capacity will eventually grow at the same rate, and, starting from any given initial conditions, there will be a gradual approach to the steady-state solution since the roots are positive and less than one.

Steady-state solutions at various assumed output growth rates yield unrealistic amounts of excess capacity at low growth rates, but implied excess-capacity percentages fall sharply as output growth rates rise.<sup>6</sup> The unrealistic solutions reflect the fact that the equations were fitted during a period of increasing excess capacity, in spite of an average 4.5 per cent growth of output. The McGraw-Hill steady-state solutions are much more unrealistic than the de Leeuw solutions because the McGraw-Hill capacity index implies a much greater increase over the period in excess capacity.<sup>7</sup> The McGraw-Hill solutions imply great insensitivity of investment to excess capacity, the de Leeuw solutions a considerable degree of sensitivity. Both sets of equations indicate that output growth rates strongly affect the steady-state solutions.

Iterations of the McGraw-Hill and de Leeuw equations fitted to 1950-62 data, on six different output growth assumptions, are summarized in Table 3. Given the 1962 initial conditions, the first three examples compare fluctuating growth rates with the equivalent steady growth rate. The annual percentage increases in the first two examples are those which occurred from 1953-63; the order has been rearranged to start with the approximate 1963 increase in each case, and yet to follow a pattern of fluctuations similar to that from 1953 to 1963. The third example assumes the equivalent steady growth rate from 1953 to 1963. With fluctuating output growth, investment also fluctuates; steady output growth leads to increases in investment each year. Although these three examples do not warrant generalizations about the effects of steady growth rates, compared to any possible series of fluctuating rates which result in the same total growth, they do suggest that steady growth is likely to produce more investment than

<sup>6</sup> At a zero rate of growth of output the McGraw-Hill equations lead to 50 per cent excess capacity, the de Leeuw equations to 32 per cent.

<sup>7</sup> From 1949-52 to 1959-62 the average percentage of excess capacity implied by the McGraw-Hill index rose 300 per cent and that implied by the de Leeuw index 25 per cent. See Table 6.

TABLE 3—(Continued)

fluctuations of the character experienced from 1953 to 1963. The equations based on the de Leeuw index are more sensitive to output growth rates than those based on the McGraw-Hill index, in the sense that the percentage changes in the steady-state solutions for excess capacity are much greater as the assumed output growth rates rise.

The four examples assuming steady output growth rates indicate that, given 1962 initial conditions, higher growth rates would produce much more investment and much higher ratios of investment to output over the next 10 years. Both the McGraw-Hill and de Leeuw equations show that investment is very sensitive to the output growth rate; the de Leeuw equations are somewhat more sensitive in the sense that the percentage changes in average investment are somewhat higher as output growth rates increase. Sensitivity to excess capacity, on the other hand, is much greater with the de Leeuw index than with the McGraw-Hill index, as already indicated by the steady-state solutions. The percentages of excess capacity reached in 1971 and 1972 bring out the extreme insensitivity to excess capacity of the McGraw-Hill equations. At the 4.5 per cent steady rate of growth, the approximate equivalent of the fluctuating output increases from 1949 to 1962, excess capacity continues to increase with the McGraw-Hill equations, and at 5 per cent it remains at the 1962 level; with the de Leeuw equations at these growth rates excess capacity is lower in 1972, and at 5 per cent growth the steady-state solution of 10 per cent excess capacity is already reached.

### *V. Industry Investment Equations*

The industry investment equations fitted to 1950-61 data, shown in Table 4, are listed roughly in the order of reasonableness of the equations. The first eight equations are fairly satisfactory. The coefficients of the independent variables have appropriate signs; all of the coefficients of the excess capacity and capacity terms are significant at the .05 level, but in two cases the coefficients of the change in output term are not. The correlation coefficients are about as high as can be expected from such a simple model. The standard errors of estimate of the equations are below 10 per cent of the mean investment in all but two cases, and only slightly higher in those cases. In only one of the first eight equations is there any evidence of autocorrelation of residuals.<sup>8</sup>

The first eight industries accounted for 56 per cent of investment in 1954, the last five industries for 29 per cent, and industries for which data are not available, the remaining 16 per cent of manufactur-

<sup>8</sup> Since the equations do not pretend to fully explain investment, it is not surprising that there is some evidence of autocorrelation of residuals. On the whole the coefficients do not seem to be biased on this account.

ing investment.<sup>9</sup> The reasons why five industries gave poor results are analyzed below.

### VI. *Analysis of Coefficients*

The coefficients of the equations for total manufacturing and for the 13 industries appear unreasonable at first glance. The excess-capacity coefficients in some cases seem much too high, and the coefficients of the  $C_{bt}$  term in most cases seem too high. The high coefficients reflect the fact that capacity is measured in 1954 value added by manufacture-output terms, rather than in capital stock terms. A million dollars of capacity is the capital stock needed for one million dollars a year of value added by manufacture. When the coefficients are roughly adjusted to capital stock terms, they seem quite reasonable (Table 5). The adjustments were made as follows. The estimates of net capital stock in constant 1954 dollars of the National Industrial Conference Board for the years 1953 and 1955 were used to calculate ratios of net capital to value-added output; the lower of the two ratios thus calculated was assumed to be closer to the full-capacity output ratio; the lower ratio was then converted to a gross capital to value-added ratio by means of the relation between the appropriate new Department of Commerce gross and net capital stock estimates for 1953, in constant 1954 dollars.<sup>10</sup>

The ratio of gross capital to value-added for manufacturing seems reasonable. Furthermore the coefficients in the equations for total manufacturing seem reasonable when roughly adjusted to the capital stock basis. In both the McGraw-Hill and de Leeuw equations the speed of adjustment to excess capacity is approximately one-sixth of the excess capacity; the de Leeuw equation shows somewhat greater speed of adjustment. The coefficient of the  $C_{bt}$  term, meant to measure replacement investment, when adjusted to the capital stock basis seems highly reasonable in the de Leeuw equation (5.5 per cent), but is still

<sup>9</sup> The industries for which comparable capacity and output data were not available are other fabricated metal products and various miscellaneous groups such as furniture and apparel. Two of the three industries accounting for the most investment are in the first eight, petroleum and chemicals; the third, motor vehicles, is in the last five industries.

<sup>10</sup> The NICB net estimates are in [2], App. II, Table A-2. The NICB net estimate for total manufacturing is \$95.5 billion for 1953, assuming straight line depreciation; the U.S. Commerce Dept. estimate is 58 billion 1954 dollars for 1953, assuming straight-line depreciation and Bulletin F lives. The principal reason for the higher NICB figure is that their data are on a company basis, rather than on an establishment basis, but there are other important differences in sources and methods. Since the data on plant and equipment expenditure are also on a company basis, the NICB figures for individual industries may not be much too big. The U.S. Dept. of Commerce gross figure for 1953, on the same basis, was 125 billion 1954 dollars, so each of the net ratios was multiplied by a factor of 2.2 to convert it roughly to a gross basis. This amounts to assuming equal plant and equipment lives in all industries. For U.S. Commerce Dept. estimates, see [3].

Symbols:

 $C$  = capacity $Y$  = output $C_{0t}$  = capacity at beginning of year

much too high in the McGraw-Hill equation (8.8 per cent). This is the most important difference between the two equations. The coefficients of the change in output terms are almost identical and suggest that manufacturers plan to expand capacity up to only 9 per cent of the addition to output. Direct effects of output changes are small, but it must be remembered that additions to output decrease excess capacity, and therefore increase investment, and that higher investment increases total capacity, and therefore in turn leads to more replacement investment, but also more excess capacity. The sensitivity of investment to output growth rates brought out in the steady-state solutions and iteration examples results from the direct and indirect effects of the output growth rates assumed. The high coefficient of the  $C_{b1}$  term is primarily responsible for the much higher excess-capacity solutions of the McGraw-Hill equations.

Since the de Leeuw equation results in more reasonable coefficients and more reasonable steady-state solutions for total manufacturing than the McGraw-Hill equation, a further adjustment of the industry equation coefficients may be in order because they are based on McGraw-Hill capacity data. Columns 4 and 7 of Table 5 adjust the coefficients in the industry equations to a "de Leeuw basis." Both of the adjustments made in the coefficients are very rough, but it is abundantly clear that coefficients in the industry equations that seemed completely out of line and unreasonable fall into line when adjusted. The capital stock adjustment is much the most important, except for the  $C_{b1}$  term. In that case the adjustment to the "de Leeuw basis" is also substantial and leads to more reasonable results.

An analysis of the adjusted coefficients brings out the fact that the first eight industries, for which the equations gave good results, are much more sensitive to excess capacity than the last five, and also much more sensitive directly to changes in output. The lower sensitivities are not enough by themselves to explain why the last five equations are not good fits, but they are consistent with the explanation offered below.

### VII. *Industries with Poor Results*

The last five industries, for which the equations gave poor results, include consumers' goods and producers' goods, industries in which demand is stable, and industries in which demand fluctuates violently. Particular circumstances might explain why each of these industries gave poor results.<sup>11</sup> But a more general explanation seems more con-

<sup>11</sup> Some of these might be strikes in iron and steel, defense contracts in transport equipment excluding motor vehicles, and the difficulty of measuring capacity in an industry like food and beverages. Statistical problems may explain the poor results in some cases; for

13. Food and Beverages	11.15	14.66	18.33	21.75	16.47

vincing. These industries tended to have the highest percentages of excess capacity, excluding food and beverages, in recent years (see Table 6). In fact for all 13 industries there is a rough rank correlation between the percentages of excess capacity and the satisfactoriness of the equations.

The absolute magnitude of the excess-capacity percentages shown in Table 6 for individual industries must be considered in the light of the fact that they are based on McGraw-Hill capacity indexes, and that for total manufacturing the percentages of excess capacity in recent years which are implied by the McGraw-Hill index are unreasonable, out of line with reported operating rates, and much lower than those implied by the de Leeuw index. The fact that the McGraw-Hill index rises at a much greater average rate than the de Leeuw index leads to very different patterns of implied excess-capacity percentages over time. For the early years the McGraw-Hill index implies much less excess capacity, for the later years much more.

food and beverages the simple correlation between excess capacity and total capacity was so high that meaningful results were impossible. Also in iron and steel and nonferrous metals, investment data on a company basis include important expenditures outside manufacturing establishments.

It may be suggested that the excess-capacity percentages in the various industries could be adjusted to a "de Leeuw basis," as the coefficients were. This procedure does not seem appropriate, although some rough adjustment may be necessary in the over-all magnitudes. The ranking of industries according to which excess-capacity percentages are the highest would not be affected by such an adjustment, of course. Furthermore, it is well known that very substantial excess capacity existed in at least two of the industries with the highest indicated percentages of excess capacity, iron and steel and motor vehicles.

Whatever the absolute size of the excess percentages in the various industries, the industries with poor results tended to show the highest percentages, on the average, in recent years.<sup>13</sup> These high levels of excess capacity might be the result of low sensitivity to excess capacity and to changes in output, as indicated by the equation coefficients. But it seems much more reasonable to believe that the insensitivities are due to the very high levels of excess capacity in recent years. Reactions to excess capacity may be small when output is near preferred operating rates, and the excess capacity is expected to be temporary. But when excess capacity is 20 or 30 per cent of total capacity for several years in succession, changes in the degree of excess capacity may have almost no effect, and the excess capacity may in fact lead to precisely the type of modernization and cost-reducing investment which cannot be explained by accelerator-type forces.

### VIII. *Conclusions*

1. Linear regression equations for total manufacturing satisfactorily explain most of investment since 1950. The current year's investment is explained by the previous year's excess capacity, total capacity at the beginning of the year (to allow for replacement investment), and the current year's change in output.

2. Equations based on 1950-61 data for total manufacturing and for 13 individual industries performed well in most cases as estimators of 1962 investment. Equations for total manufacturing did not perform so well in estimating 1963 investment.

<sup>13</sup> The average excess capacity for manufacturing as a whole is strongly affected by the five low-ranking industries. The excess-capacity calculations in Table 6 are based on output measures of capacity, and the five low-ranking industries accounted for roughly 30 per cent of manufacturing value-added in 1954, while the eight high-ranking industries accounted for 40 per cent, and uncovered industries for 30 per cent. The relative importance of the three groups of industries for investment expenditures was very different.

The precise meaning of the excess-capacity percentages is not clear, since the definitions of capacity are not clear or precise.

3. Equations for total manufacturing were fitted for 1950-61 and also for 1950-62, using both the McGraw-Hill and the de Leeuw indexes of manufacturing capacity. The de Leeuw equations are better fits and performed better as estimators. Equations relating capacity increases to investment led to much closer and more significant relations with the de Leeuw index than with the McGraw-Hill index.

4. Equations for total manufacturing investment and capacity were combined to form second-order difference equations in capacity and were used to analyze the effects of various output growth rates on investment and excess capacity. Both fluctuating and steady growth rates were assumed, and steady-state solutions were compared with the results of iteration examples starting from 1962 initial conditions. Fluctuating output growth rates seem to produce less investment and lower ratios of investment to output than the equivalent steady growth rate. Both the steady-state solutions and the iteration examples indicate that investment is highly sensitive to the assumed rate of growth of output.

5. Equations based on the McGraw-Hill index of capacity imply that investment is highly insensitive to the degree of excess capacity. Even at 4 or 5 per cent a year rates of growth of output, excess capacity would tend to increase and reach unrealistic levels. The equations based on the de Leeuw index give a very different picture in this respect. Steady growth rates of 4.5 or 5 per cent would tend to reduce excess capacity, compared to average 1959-62 levels, and the amounts of excess capacity implied are reasonable. The strong upward bias in the McGraw-Hill index accounts for the very different results.

6. The coefficients of the equations for total manufacturing and for the 13 industries appear reasonable when they are roughly adjusted to capital stock estimates of capacity, rather than the value-added output measures of capacity used in the original equations. The coefficients of all three terms are of reasonable orders of magnitude, except for two or three industries for which the equations are completely unsatisfactory.

7. Of the 13 industries tested, reasonably satisfactory equations were fitted in eight cases. These eight industries account for 56 per cent of manufacturing investment in 1954. The five industries for which the equations were unsatisfactory present certain statistical problems which may explain the results. However, a more general explanation seems highly plausible. These five industries have experienced the highest percentages of excess capacity since 1956. These are such high percentages, even when adjusted to correct for the upward bias in the McGraw-Hill indexes, that accelerator-type forces could hardly be expected to explain investment.

## STEEL IMPORTS AND VERTICAL OLIGOPOLY POWER

By WALTER ADAMS AND JOEL B. DIRLAM\*

The so-called steel-import problem, largely a phenomenon of the 1950's, is an amalgam of several causes—the recovery from wartime destruction and dismantling of the European and Japanese steel industries; the installation of ultramodern capacity, reflecting latest technology, outside the United States; a substantial increase of world-wide capacity; a generally export-oriented price policy by European and Japanese producers; a generally insensitive, utility-like, administered price policy by domestic producers. In other words, the steel-import problem is the product of the comparative showing of the U.S. steel industry in an increasingly competitive world economy.

Some basic data on the performance of the domestic industry will make the point:

1. Between 1955 and 1962, U.S. production of steel ingots decreased from 117 million tons to 98 million tons. At the same time production in the rest of the Free World increased from 112 to 175 million tons, in the Communist bloc from 68 to 126 million tons, in the world as a whole from 297 to 399 million tons. The U.S. share of world steel production declined from 39.4 per cent in 1955 to 24.6 per cent in 1962—an unbroken decline in this country's relative share [16, p. 336].

2. The same deterioration is observable in this country's steel-export position—both in absolute terms and in comparison with the world's major steel-exporting countries. Between 1954-56 and 1961, the U.S. share of world export markets (outside the United States itself) declined from 20.0 to 10.1 per cent, while that of the Common Market increased from 53.9 to 62.5, that of the United Kingdom declined from 12.7 to 11.3, that of other European OECD nations increased from 7.2 to 9.9, and that of Japan remained stable at 6.2 per cent. This decline in the U.S. share would appear even greater if tonnage rather than value figures were used; and also it presumably would have been greater but for the artificial stimulus to U.S. steel

\*The authors, professors of economics at Michigan State University and University of Rhode Island, respectively, are indebted to Professor Anthony Koo for his counsel, to Pierre de Raet for his statistical computations, and to Alfred E. Kahn for his extensive comments.

exports by the "Buy American" strings attached to some of our foreign aid programs [16, pp. 490-91].

3. This loss of world export markets by the U.S. steel industry was accompanied by a historically notable invasion of the industry's domestic market by foreign producers. Whereas the United States was traditionally a net steel-exporter, its position was dramatically reversed starting in 1959 (a strike year). Since then, the United States has been a net steel-importer. Whereas in 1955 the United States exported four times as much steel tonnage as it imported, by 1962 it imported twice as much as it exported [16, p. 327].

4. In terms of capacity utilization, i.e., operating rate, the U.S. steel industry also compared unfavorably with the world's major steel-producing countries. The following data make the point [16, p. 339]:

PERCENTAGE UTILIZATION OF STEEL CAPACITY IN SELECTED AREAS, 1955-62

Area	1955	1956	1957	1958	1959	1960	1961	1962
United States	92.1	88.0	82.2	59.2	63.1	66.3	64.5	63.8
United Kingdom and ECSC	96.7	96.2	94.8	85.0	87.7	95.2	89.5	84.4
Japan	N.A.	N.A.	70.6	67.0	90.1	96.4	97.5	82.6

5. In terms of technological innovation, the U.S. industry also lagged behind its foreign competitors. During the 1950's, according to *Business Week* [7, pp. 144-46], "the industry bought 40 million tons of the wrong kind of capacity—the open hearth furnace," while the Europeans and Japanese were installing the cheaper and more productive oxygen converters at a breakneck pace. Ironically, much of the U.S. industry's current investment in plant and equipment is calculated not to add to capacity, but to correct the embarrassing investment errors of the last decade.

6. While foreign producers priced their steel in accordance with the fluctuating vicissitudes of the world market [16, pp. 29, 476, 482], U.S. producers followed an administered price system characterized by upward flexibility. Thus, according to the Bureau of Labor Statistics, the U.S. wholesale price index for iron and steel products increased 88 per cent between 1947 and 1958, while the wholesale index for all commodities (other than farm and food) increased only 32 per cent. From World War II to 1958, "the steel price index continued its virtually unbroken rise even when demand and production declined (as they did in 1949, 1954, and 1957). It also continued its climb even when unit labor costs declined (as they did in 1950 and 1955). No matter what the change in cost or in demand, steel prices since 1947 have moved steadily and regularly in only one direction,

upward" [17, p. 129]. The fact that prices were raised in 1957 and 1958, and subsequently maintained in the face of declining demand, operations at less than 60 per cent of capacity, and in the midst of a general recession; the fact that the industry again attempted to raise prices in April, 1962, with operations lagging at 50 per cent of capacity and the economy far from full employment—these are further indications of the perversity with which the U.S. steel industry reacted to the environmental influence of market conditions.<sup>1</sup>

Clearly, no internal domestic forces have been sufficiently powerful to ameliorate the questionable performance of the U.S. steel industry. Not the discipline of market competition, nor the pressure of public opinion, nor the corporate soul of industry executives, nor the castigations of the Kefauver Committee have succeeded in promoting more competitive behavior. Repeatedly the industry has been urged to reduce prices in order to increase sales, recapture foreign business, stem the import tide, reduce the threat of competing materials, operate at higher levels of capacity, and thus cut unit costs [18, pp. 27-87]. But the industry persisted in its belief that the demand for steel was inelastic and behaved as if this inelasticity applied even in markets where steel was confronted by competition from substitutes and imports.<sup>2</sup>

The industry's behavior in the face of substantial imports seemed to belie the Mancunian assumption among policy makers that "free international trade is the best antimonopoly policy and the best guarantee for the maintenance of a healthy degree of free competition."<sup>3</sup> It is important, therefore, to determine why the ostensible discipline of imports proved to be ineffective.

It is our contention that a vertically integrated oligopoly must maintain its administered price structure with all the economic and political weapons at its disposal. It must defend *à outrance* the vertical succession of keystone prices on which the entire price system rests. It must, therefore, contain, insulate, neutralize, and sterilize imports, especially

<sup>1</sup> This is not to gainsay the fact that transaction prices occasionally deviate from quoted prices, that there is some off-list selling, and that there are some temporary (though short-lived) dips in the steel index. The trend of the steel price structure, however, is unmistakably and unidirectionally upward.

<sup>2</sup> Indeed, during the latest round of "selective" price increases, its spokesmen felt that these increases would "spur demand, instead of retarding it." See "Price Hikes May Spur Demand," *Steel*, Oct. 7, 1963.

<sup>3</sup> Gottfried Haberler, quoted in [12, p. 34]. However, on the basis of a multiple regression analysis of the effect of quantity and price of imported steel products on domestic prices between 1954 and 1958, Krause concluded that "the foreign trade variables were not very important in determining changes in domestic steel prices" [12, p. 41]. Unfortunately, Krause did not consider vertical integration as a conditioning element in the industry's price response to imports.

when they threaten the vertically interwoven strategic prices. It cannot allow imports to have more than a sporadic, peripheral, nonstructural impact. Conversely, if the entire noncompetitive price structure is to be eroded, this must be done through an attack on strategic prices. Only if imports are pinpointed at the focus of vertical price policy (i.e., strategic prices) can they trigger price competition in the unconcentrated segments of the industry. Once such price competition breaks out among the independents, the vertically integrated oligopolists are compelled to meet it—at the cost of sacrificing at least a portion of the administered price structure and the rigidities associated therewith. Whether imports succeed in collapsing the entire structure depends upon the quantitative importance of the imported products, their place in the vertical hierarchy, and the staying power of the independents under a regime of dual distribution.

We propose to demonstrate the validity of this hypothesis by an examination of the wire segment of the steel industry and its response to import competition between 1955 and 1962. This examination will treat (1) the extent of imports, (2) the industry's price response, (3) an explanation for the industry's differential response to raw-material and finished-product imports, (4) the industry's nonprice response, and (5) a final assessment of the import discipline hypothesis.

### *I. The Extent, Trend, and Pattern of Imports*

Steel imports into the United States since 1955 have taken an ever-growing share of the domestic market—rising from 1.2 per cent of the total supply in 1955 to 5.6 per cent in 1962. Among the selected groups of steel products shown in Table 1, wire rods are by far the most important semifinished import. In 1962, for example, the import tonnage of wire rods exceeded that of ingots, blooms, slabs, and billets by a margin of roughly 4 to 1. Other large tonnage imports include pipe and tubing, structural shapes, concrete reinforcing bars, and sheet and strip. With the exception of reinforcing bars, however, none of these imports has ever accounted for more than 15 per cent of domestic consumption. Wire rods and some wire products, on the other hand, have captured substantial shares of domestic markets. It is here, first of all, that we should attempt to measure the impact of steel imports.

#### *Wire Rods*

Imported wire rods have been significant for two reasons. First, as a semifinished material imported in quantity, they threatened to disturb the vertical structure of the U.S. steel industry at midpoint, where shifts of capacity to alternative products were difficult. Second, they

TABLE 1—IMPORTS OF SELECTED STEEL PRODUCTS, 1955-62  
(000's of net tons)

Year	Ingot, Blooms, Billets, Slabs, etc.	Shapes, Plates & Piling	Reinforcing Bars	Pipe and Tubing	Sheets and Strip	Wire Rods	Wire & Wire Products	Total Steel Products
1955	146.1	111.8	158.9	77.1	54.7	47.8	245.3	973.2

1962	174.4	524.6	607.3	654.7	383.7	644.6	655.2	4,100.4

Source: AISI, *Foreign Trade Trends, Iron & Steel*, 1963 edition.

captured a large share of the noncaptive U.S. wire-rod market—that is, rods consumed by firms purchasing, but not producing, rods. The import share of this noncaptive market had reached 17.1 per cent as early as 1958, 39.2 per cent in 1962, and promised to exceed 40 per cent in 1963.

When imports are compared with the total U.S. production of wire rods, their significance shrinks. In 1962, imports amounted to no more than 14.5 per cent of total wire-rod output. This low percentage compared with the share of marketed wire rods reflects the structure of the industry; over the years the vast majority of wire rods have been further fabricated by the firms that produce them, as shown by Table 2. Imports have loomed large only when compared with the noncaptive market.

Wire-rod imports have a third distinguishing characteristic. During the years 1957-62, they increased faster than those of any other steel product. As shown by Table 2, the tremendous acceleration in imports was not accompanied by a parallel growth in U.S. output of wire rods. It seems reasonable to conclude, therefore, that the imports appropriated what would otherwise have been a 400-500 thousand-ton growth in the market for domestically produced wire rods, and that the U.S. markets captured by imports were those belonging to the domestic integrated mills, the giants of the steel industry.

### *Wire Products*

The imports of the most important products of the wire branch of the steel industry, together with their proportion of estimated domestic consumption, from 1955 through 1962, are shown in Table 3. The

table brings out the relative importance (in tonnage terms) of imports of wire and nails, with other wire-product imports such as barbed wire and wire fencing running far behind. When the proportions of imports to domestic consumption are considered, however, barbed wire and wire fencing are high on the list, while wire itself<sup>4</sup> in 1962 amounted to no more than 9 per cent of domestic consumption. Nevertheless, to the extent that wire is an intermediate product in further fabrication (since it may be galvanized and be sold as fencing wire, or woven into woven wire fence, or made into chain link fence), even the relatively low volume of wire imports has disturbed integrated or partially integrated firms selling wire on the domestic market.

### *Conclusion*

The products representative of every stage of the wire division of the steel industry have been increasing their absolute import tonnage into the United States since 1955, but at differential rates. For our purposes, it is sufficient to note that in 1955 wire rods constituted only about 16 per cent of all wire imports into the United States, whereas by 1962 this percentage had climbed to almost 50 per cent. Whether or not this phenomenon can be explained in terms of the industry's differential price response is discussed in the following section.

### *II. The Price Response to Imports*

The response of the U.S. steel market to wire-rod and wire-products imports is illustrated in Table 4 and Chart 1. Table 4 presents BLS price indices for wire rods, drawn carbon wire, welded wire fabric, bale ties, chain link fence, woven wire fence, nails and barbed wire, with 1955 as the base year.

The pattern of response makes an interesting contrast with the trend of imports. The price of wire rods moved up in each year from 1955 through 1959 and remained unchanged through 1962. Carbon wire prices followed the same time sequence of changes, but the 1959 high did not represent such a steep rise from 1955 as the wire-rod high. Prices of many products, by contrast, seem to have reached a peak about 1958 and to have declined thereafter. Without further discussing the details of price movements, it is clear that the raw material—wire rod—and the semifinished material—wire—both rose in price more than fabricated products and were later maintained in price, while the fabricated products were not. This has led to widespread allegations by nonintegrated fabricators that their integrated

<sup>4</sup> "Wire" includes many varieties. Unfortunately, Census statistics do not show separate shipments or consumption of multifarious types of wire used in different end products.

\* January 1955=100.

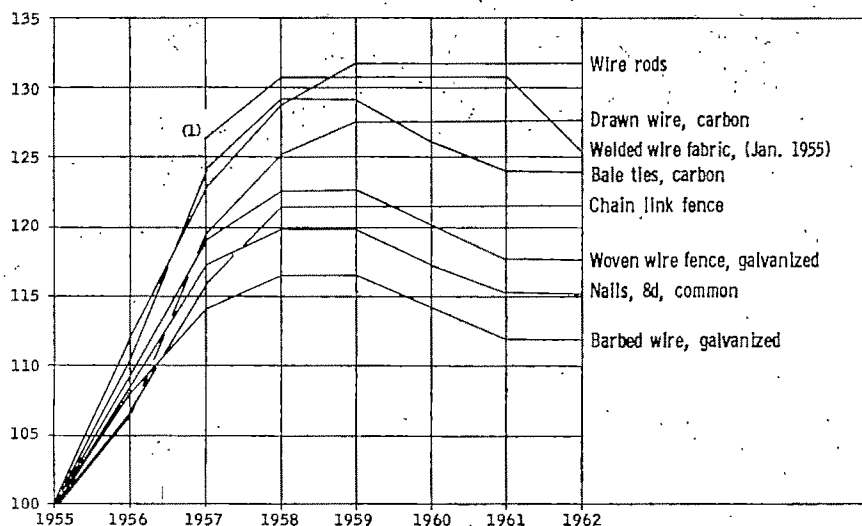

Source: Recomputed from Bureau of Labor Statistics, *Wholesale Prices and Price Indexes*, using 1955 as a base.

Notes: The price of welded wire fabric was not included among the BLS sample of wholesale commodities until 1957, although the index was computed on a January 1955 base. In the years 1960-62, published prices have not been representative; a large proportion of sales has been made on a negotiated basis, and at prices lower than indicated by the BLS index.

Although chain-link-fence prices appear to be accurate for sales by mills to jobbers, prices charged by nonintegrated mills directly to consumers (and these account for most of their sales) have often been less than 50 per cent of the prices used in the BLS index for the years 1961-62.

It should be noted that, with one exception, BLS respondents are all integrated mills making wire rods.

rivals were applying both a simple and (after 1959) a double price squeeze [19, pp. 224-373].

### Wire Rods

There are two features of wire-rod price behavior that stand out most sharply against the dramatic increase in imports. First, through 1962, the price of wire rods rose *more* than the price of any other steel product surveyed by the Bureau of Labor Statistics in the post-war period [16, p. 234]. It was the most "upward mobile" steel price in the industry's administered price complex. This in itself is curious, not only because half the postwar rise took place in 1955-62, when imports were increasing, but because there was a persistent unutilized capacity in wire rods from 1956 on—an excess that came close to 40 per cent. The second feature is the price inflexibility, 1958-62, when imports of wire rods were rising at an average annual rate of over 60 per cent.

There are exceptions to the above generalizations, but they are so slight as to underscore the extraordinary behavior of wire-rod prices. One firm, Colorado Fuel and Iron, with an unusually large part of its investment in wire-rod capacity, attempted (apparently in 1958 and

TABLE 5—IMPORT AND DOMESTIC PRICES FOR WIRE RODS  
1958-62<sup>a</sup>

Source: *Steel* magazine.

<sup>a</sup> Imports from Western Continental Europe; imported wire rods are Thomas quality. Imported open-hearth wire rods are usually quoted \$4-10 above the Thomas-quality rods.

<sup>b</sup> *Steel* magazine quotes the price for January and February. Price is quoted as "nominal" from March through August. The series is discontinued after August, 1962.

1959) to make concessions to retain wire-rod customers. It soon abandoned such attempts.<sup>6</sup> Also, there is reason to believe that a few other integrated firms have made sporadic concessions on wire rod, but their quantitative significance was *de minimis*.<sup>7</sup>

Over a five-year period, when domestic prices were perfectly rigid at \$144.50 per ton, comparable foreign wire rod was being sold at \$110, \$105, or, at times, even less than \$100 per ton.<sup>7</sup> Table 5 shows

<sup>6</sup> According to its vice-president in charge of sales, "When C.F.&I. found that its wire rod customers were changing to foreign rods because of the lower price, we attempted to be at least partially competitive with these lower prices. The extent of our competitive price varied, depending on the competitive necessity in each particular case. Although our competitive prices were partially successful, in many cases we lost customers to foreign rods because they were purchasing at prices lower than those which we could meet" [20, CF&I, p. 6]. The stated opinion of the other integrated steel companies was that any reduction they might make in rod prices would be followed by their foreign competitors, and hence prove self-defeating [20, Armco, p. 6; Youngstown, p. 6; J & L., p. 9; Pittsburgh, p. 6]. The companies also justified their refusal to meet import prices on the grounds that the latter represented sales at less than fair value and hence were discriminatory [20, Bethlehem, pp. 7-8].

<sup>7</sup> Members of the industry claim that even though f.o.b. mill prices on wire rods were maintained, there was a decline in mill net prices because of an increase in freight absorption and a "reaching out" into distant territories to offset the import-induced loss of customers in nearby ("natural") market territories.

<sup>8</sup> In the spring of 1963, independent fabricators bought imported wire rods, Thomas quality, for \$93 per ton, and open-hearth rods for \$100-102 per ton [19, pp. 250, 351].

the margins between import and domestic prices for wire rod at representative ports. The evidence is incontrovertible that the domestic mills sold wire rod continuously at differentials sometimes exceeding 40 per cent above the price of imported rods. Indeed, steel-mill spokesmen were quick to boast of their unwillingness to meet foreign competition. There was, in short, no domestic price response to wire-rod imports.

### *Wire*

The rigidity in the price of wire, after a rapid increase from 1955 to 1958, is brought out in Table 4. The integrated steel firms pointed with pride to the maintenance of wire prices in the face of imports. Users of wire, they insisted, could count on the integrated firms preserving a fair spread between manufacturers' bright wire and the more expensive varieties [20, J & L, pp. 9-10].

At the same time that the large integrated wire producers (who accounted for well over half of the wire shipments) were maintaining prices, imports of wire were available at margins substantially below the domestic price. In 1963, at North Atlantic ports, manufacturers' bright wire sold at about \$20 a ton below the domestic product, while imported galvanized fencing wire was sold at an even greater differential.

Until recently, the failure of the domestic integrated firms to respond to the lower price of imports did not seriously affect their volume of wire sales, although it did contribute to the erosion of their noncaptive market for wire rod. In the market for wire, it seems, there have been a number of nonprice considerations that led potential customers of imported wire to prefer domestic sources even at substantial premiums.<sup>8</sup>

The rigidity of wire prices, therefore, may be tentatively ascribed to two aspects of the U.S. market: the dominance of the vertically integrated firms, who avowedly wished to maintain differentials and levels in the wire market, and the relatively small impact on U.S. sales of low-priced wire imports.

### *Wire Products*

Prices of representative wire products as shown in Chart 1, and Table 4, have fallen since 1958 and 1959, compared with the price of

<sup>8</sup> Some wires, like plating wire and certain varieties of bright wire, are not readily imported because they must be free from surface blemishes due to oxidation. Other wires are shipped on huge carrier spools, and hence do not lend themselves to shipment from abroad. Moreover, many wire purchasers buy in small quantities, often as little as 50-100 lbs. Such customers cannot easily or accurately forecast their needs months ahead of delivery, and warehouses are unwilling to stock vast varieties of specialty wire to accommodate these "retail" purchasers.

wire rod and wire, producing the "double squeeze" that has accelerated the fabricators' move toward imported rod.

Here again, as in the case of rods, the movement of domestic-products prices cannot be correlated with the import pattern and, indeed, shows signs of perversity. Barbed wire and nail prices declined, but it is far from evident that the drops should have come when they did, since imports had been a substantial factor as early as 1955. By the time these price declines became manifest, several integrated firms had permanently abandoned sizable segments of the barbed wire and nails markets, and the capacity devoted to it. Also, the price decline in chain link fence and welded wire fabric could hardly have been caused by imports, since neither product came from abroad in significant commercial quantities. On the other hand, the import of bale ties and automatic baling wire may have had an impact on the domestic price level, because these imports accounted for roughly 22 per cent of total U.S. consumption in 1962.

Summing up, there was no correlation between the proportion of imports to domestic open-market consumption and the degree of price response. Wire-rod and wire prices moved perversely to rising imports. Chain link fence and welded wire fabric prices tumbled, though imports were inconsequential. The apparent paradox, we submit, can be explained only by the structure of the industry—a subject to which we now turn.

### III. *Explanation of the Price Response*

#### *Vertical Integration and Prices*

In order to understand the pattern of response of steel prices to imports—or, perhaps more aptly, to understand that there is a pattern of response in what seems to be inconsistency—it is necessary to begin with an analysis of steel pricing and its principal determinants. As is only natural, the structure of the steel industry plays a large part in shaping its price behavior.

First, steel is an oligopoly in the horizontal sense. A relatively small number of firms sell the most important semifinished and finished products. Four firms, for example, produce 71 per cent of steel ingots, 56 per cent of sheet and strip, 64 per cent of hot rolled bars, 65 per cent of pipe and tubes, etc. In this oligopoly, the accent is on price uniformity and price stability. Cost movements and target returns—more so than demand—are prime determinants of price policy, perhaps because of the industry's expressed belief that the market for steel is price-inelastic [10, pp. 13-24].

The steel industry is, of course, vertically integrated as well. Its oligopolistic structure strongly influences the vertical relationship of

prices. If integration were complete, market prices of raw and semi-finished materials would disappear, but because at every stage of production there are incompletely ("disproportionately") integrated firms that purchase products for further fabrication or conversion, these intermediate prices are present in the steel-pricing structure. Pricing policy of the steel industry, and of its price leaders, includes, therefore, not only the achievement of goals set for individual prices, but also maintenance of the proportions, ratios, and margins between prices at successive levels of production that seem to be in the best interests of the industry.

Some of the prices in the vertical steel price structure are of more importance than others. These are what we have earlier called strategic prices. They are the keystone on which a portion of the price edifice rests. If they change, it will be necessary to shift the entire structure. Like the Gulf Coast or Group 3 spot prices for gasoline, they serve as a "peg to hang the price structure on."<sup>9</sup> Thus the price for wire rods is strategic because it is the base on which the super-structure of wire and wire-products prices are built.

If the steel oligopoly lived in a hermetically sealed world, it could maintain what it regards as the appropriate relations among prices in the vertical sequences with little difficulty. But no such world exists. The oligopoly has to permit the price structure to respond to outside stimuli, which constantly threaten it at various points. Some of the exogenous forces can be ignored as temporary aberrations. Others may be "contained" by minor adjustments. When a strategic price is threatened, however, the threat must be dealt with at almost any cost, not simply because of the necessity for re-evaluating the specific price, but because of the danger to the market structure dependent upon it.

The vertically organized giants in the steel industry, therefore, seldom consider a price in isolation. A change in any price introduces uncertainties up and down the line. If a product price is reduced, sales of semifinished steel may fall off because fabricators' margins have been compressed. The same consequence can result from

<sup>9</sup> U.S. vs. Socony-Vacuum Oil Co., 310 U.S. 150 (1940), p. 192. See also [8, pp. 386-427]. Vertically integrated steel companies, like the major oil companies, are partially dependent on the sale of an intermediate product to customers with whom they compete. The integrated oil companies dispose of unbranded gasoline to independent distributors in order to run their refineries at close-to-capacity levels. They tolerate "conventional" price differentials between their own and the independent gasolines, but they are quick to support retaliatory action whenever an independent attempts to enlarge his tacitly fixed market share through price cutting. Neither in oil nor steel, can nonintegrated customers be allowed to get out of hand. Otherwise the price level of final products may be reduced, with no increase in sales, and with the burden falling on the integrated companies at the intermediate product stage.

an increase in prices of semifinished materials while product prices remain unchanged. The vertically integrated firms must consider these aspects of policy because they sell varying proportions of their products to nonintegrated firms at different stages of production. Their own customers may compete directly or indirectly with them on the finished product. Yet, for a variety of reasons associated with the individuality of customers and vagaries of location and technology, it does not ordinarily pay to eliminate all outside sales. For all these reasons, a decision to meet or not meet the lower price of a semifinished steel product cannot be made by integrated giants simply on the facts about direct costs and extent of unutilized capacity for that product alone.

The nonintegrated fabricator, on the other hand, lives in an entirely different world. He is aware of the vertical structure of prices only insofar as it affects his margin. When the margin is disturbed—increasing or decreasing—he will respond. But in normal times he lives within the margins permitted by the structure and cooperates with its preservation by not undercutting the prices of fabricated products published by his suppliers of raw or semifinished materials.

The small firms usually refrain from endangering the price structure because they, too, are instilled with the “standard cost—target return” philosophy and accept the margin that is left to them. They understand the power and influence of the firms shaping the price structure. Nevertheless, their shorter investment and price policy time-horizon, and their lack of sensitivity to the vertical price relationships gives them a sense of irresponsibility. It makes them a source of potential danger to the structure.

### *Wire-Rod Pricing*

The pricing of wire rods, wire, and wire products illustrates the imperatives of vertical integration—the manner in which industry structure tends to determine price behavior. At the top of the “wire rod-wire-wire products” pyramid are 15 integrated producers. Of these, 12 firms, including such industry giants as U.S. Steel, Bethlehem, and Republic, account for 93 per cent of rod capacity. Without imports, their control over the wire-rod stage of the industry seems secure; entry is effectively deterred by the cost of erecting a wire-rod plant (\$20 million) [19, p. 67] and the persistence of excess capacity almost equal to U.S. production of wire rods. But, as Table 6 shows, the integrated firms also have very substantial capacity in wire products. Indeed, they customarily dispose only of some 20 per cent of their wire-rod output on the open market, the rest going into their fabrication plants [19, pp. 99-107]. Put differently, the principal con-

TABLE 6—CAPACITY AND PRODUCTION, WIRE ROD, WIRE, AND SELECTED WIRE PRODUCTS

1957-1960  
(in net tons)

Products	1957			1960		
	Capacity	Production	Production ÷ Capacity	Capacity	Production	Production ÷ Capacity
Wire rod	7,374,850	4,695,595	63.7%	7,340,480	4,265,289	58.1%
Plain wire	7,235,160	3,680,871	50.9%	7,256,320	3,263,110	45.0%
Galvanized wire	1,771,740	376,204	21.2%	1,613,890	348,658	21.6%
Nails and staples	1,263,480	481,427	38.1%	1,155,960	368,914	31.9%
Barbed wire	576,590	58,793	10.2%	388,790	48,613	12.5%
Woven wire fence	985,650	210,965	21.4%	835,570	115,033	13.8%
Reinforcing fabric	578,420	N.A.	—	1,115,760	N.A.	—
Bale ties	137,860	22,062	16.0%	123,050	14,820	12.0%

cern of the integrated firms is not with wire rods, but with the whole wire segment of the steel industry. They cannot afford to think of any one price in isolation—at the peril of disturbing the price structure and introducing uncertainties.

At the next stage of the industry, some 150 firms in 1958—and probably twice that number in 1962—purchase wire rod and draw it into wire. These firms sell wire and, in many cases, also engage in further fabrication of wire products. They account for less than half of the open-market sales of wire, and hence tend to disregard the impact of their behavior on the industry's vertical price structure. Entry into this phase of production seems to be relatively easy as the backward integration of many wire-products producers between 1955-62 tends to indicate. In no case, however, did this backward integration reach as far as the wire-rod phase of the production process.

Finally, there are the fabricators who buy wire and who make hundreds of wire products sold to industry and the ultimate consumer. These firms number perhaps 1,200-1,300—and it seems likely that the Census underestimates the total. These wholly nonintegrated fabricators—manufacturers of such items as upholstery springs, paper clips, safety pins, and coat hangers—are totally unconcerned with the industry's vertical price structure, except to the extent that this structure implies an expansion or compression of the margin between the price of the wire they buy and the price of the products they sell. This segment of the industry is markedly unconcentrated.<sup>10</sup> Entry is easy, and price competition is not foreclosed by oligopoly dominance. Lower raw-material costs trigger price reductions on individual transactions, and such reductions eventually bring about a lowering of the whole price level. Unless the integrated companies, therefore, can control strategic prices farther back in the production process, they cannot effectively meet competition either for disciplinary or defensive purposes; that is, they cannot prevent cost reductions from being translated into price reductions.

Given this framework, we can better appraise the price response of the "wire rod-wire-wire products" segment of the steel industry to the threat of imports. Beginning in 1955, two phenomena made their appearance: a supply squeeze and a price squeeze. Many of the integrated firms making wire rods failed to take care of their nonintegrated customers in this period of intense demand for steel. Some

<sup>10</sup> This is not to suggest that all fabricated-products markets approach perfect competition in terms of numbers of firms. Thus, some 14 fabricators account for the bulk of independently produced reinforcing mesh [22, p. 1]. Independent chain link fence manufacturers number approximately 20, but the market for this product is restricted by heavy transportation costs [19, p. 224]. On the other hand, there appear to be many more firms making other fabricated items.

small wire-drawers, therefore, looked around for a source of rods that would not disappear just when business was good and began turning to imported rods. Coincidentally, as part of successive, across-the-board, and industry-wide price increases, the big steel firms raised wire-rod prices in 1955, 1956, 1957, and 1958. Yet the price of wire and wire products, all dependent upon wire rod as a raw material, did not rise proportionately, uncomfortably reducing the percentage margin of the nonintegrated firms—at a time when wages and other costs were rising.<sup>11</sup> This, too, provided a motive for shifting to foreign wire rods.

The price response to imports differed in different stages of the wire segment of the industry, as well as among different wire products. First, with respect to wire rods, there was no price response. This was the strategic price which the integrated majors attempted to protect almost at any cost.

Second, with respect to wire products not imported in significant quantities (e.g., chain link fence and welded wire fabric), the independent fabricators were suffering from a price squeeze resulting from the disproportionate rise of domestic wire-rod prices. Given the lower price of imported rods, these fabricators turned to imported rods as a solution to both their supply and margin problems. As time went on, more and more fabricators did so. The accompanying reduction in cost led inevitably—given the lack of concern of the nonintegrated firms for the integrity of the price structure—to price shading on those products that the most competitive sector of the industry found to be price-elastic. Even though these items were not imported in appreciable quantities, the competitive drive among the fabricators sufficed to bring down the domestic price. The major integrated firms found it advisable to meet these lower prices, hoping to exercise some restraint on the smaller firms by so doing and, perhaps, to discourage them from embarking on such activities in the future. If the small fabricators realized that their integrated competitors were going to meet, on the nose, whatever prices were charged, there would be an incentive to limit cuts and to try to maintain a reasonable margin above the price of imported rods. Such seems to have been the case with chain link fence and welded wire fabric.

<sup>11</sup> Where customers were located at a considerable distance from wire-rod basing points, the delivered price of rods often exceeded the price of the fabricated product. In Miami, for example, U.S. Steel quoted wire rods at \$156 per ton, but sold the reinforcing mesh made from such rod at \$150 per ton [19, pp. 265-66]. For other evidence on the compression of the independent-fabricators' margin, including zero and negative margins, see *The Impact Upon Small Business of Dual Distribution and Related Vertical Integration*, Hearings before Subcommittee No. 4, House Small Business Committee, 88th Cong., 1st Sess., 1963, Vol. 2, pp. 438-39.

Third, with respect to those products imported in large quantities but whose domestic production is dominated by the integrated majors, there seems to have been little significant price response. In barbed wire and nails, for example, the giants did not meet foreign competition, thus abandoning a substantial market share to foreigners while maintaining the conventional margin between wire prices, on the one hand, and nail and barbed wire prices, on the other.<sup>12</sup> The independent fabricators, in turn, seem to have been content to enjoy the higher margin provided by the domestic-products price and to sell in the relatively protected geographical areas where nail and barbed wire imports cannot be sold at substantial differentials below the domestic price. Such price declines as the BLS reports in nails and barbed wire were not reflected in the published prices of the major integrated companies.

Fourth, where products were imported in such amounts as to threaten the independents (woven wire fence, automatic baling wire, and bale ties) there was a pronounced price response. The independents felt impelled to meet foreign competition, and the vertically integrated majors matched these price reductions, both to retain customers and to prevent the independents from cutting even further (and thus threatening the price structure). They claimed they did not cut to meet foreign competition because they believed this was an ineffective check on competitive inroads from abroad; the Belgians and Japanese would continue to engage in price competition with each other in the U.S. market—regardless of the price policy of domestic producers [20, Pittsburgh, p. 3; Republic, p. 7].

In general, then, in those segments of the industry where there was a competitive structure, that is, where nonintegrated firms were willing to pass on savings from foreign wire rods, prices tended to fall. But what of wire itself? Wire—or more properly wires—were never imported in substantial enough quantities to capture a significant segment of the domestic noncaptive market. Moreover, the backward integration of theretofore nonintegrated fabricators into wire drawing that occurred during the years 1958-63 did not, for the most part, lead to domestic price cutting in wire because these new entrants engaged in further fabrication; they became purchasers of imported wire rod mainly to protect themselves against the squeeze between higher wire-rod prices and lower prices for such items as chain link

<sup>12</sup> Several vertically integrated steel mills abandoned the production of products which faced import competition. Bethlehem discontinued making nails, fence, and barbed wire at its Johnstown plant [20, Bethlehem, p. 7]. Pittsburgh Steel discontinued the making of barbed wire, nails, and fencing in 1959 [20, Pittsburgh, p. 5]. In 1961, Detroit Steel withdrew from the production of building mesh, except for a few customers near its Portsmouth, Ohio, plant [20, Detroit, p. 7].

and woven wire fence. Finally, the integrated companies explicitly assumed responsibility for supporting the price structure in wire [20, Bethlehem, p. 10; J & L, p. 9]. One variety of wire—automatic baling wire—was imported in sufficient quantities at lower prices to bring a direct response from the independents and hence, the industry as a whole, as shown by the reductions in published prices in *Steel* magazine. But this was clearly an exception to the general upward flexibility of wire prices.

Why, then, did the vertically integrated major firms decide to change their own price structure—including the margins between rod and wire—by insisting on a disproportionate upward movement in rod prices during the years 1955-58, inclusive?

There are several alternative hypotheses that could shed light on the behavior of the wire-rod makers. First, and this is the hypothesis advanced by some fabricators, the vertically integrated firms were simply inept. They pursued a public-utility, cost-plus pricing policy in the conviction that price has nothing to do with sales. Thus, they tried to saddle the nonintegrated fabricators with the sunk costs of excess and antiquated wire-rod capacity. Moreover, they never squarely faced the supply problems of the nonintegrated fabricators and never fully understood the abject dependence of these fabricators on a survival margin between rod and product prices. There is an element of truth in this view.

A second hypothesis is that the squeeze—particularly the delicate but excruciating additional twist of the maintenance of rod prices between 1959 and 1962—was deliberate, and designed to rid the fabricating end of the industry of price competition by independents. This explanation cannot be wholly discarded.<sup>13</sup>

A third, and probably the most valid, hypothesis is based on the structural implications of vertical integration. Given the tapered integration and dual distribution in the wire segment of the steel industry, the majors had to compete with their nonintegrated customers. Before reducing rod prices, therefore, they had to consider not only the implications for rod revenues, but also the impact of this "cost" reduction on the independent fabricators and the indirect impact on the level of product prices. As long as the independent fabricators continued to buy domestic rod—and most of them used a 50/50 mix of imported and domestic rods in order not to cut themselves off from domestic supply sources—the majors felt that price cutting in the

<sup>13</sup> There are intimations, for example, that the integrated majors have initiated the proposal to reduce the tariff on welded wire fabric in order to tighten the squeeze on the independents [22]. The integrated companies were also complainants of record in the dumping charges before the Tariff Commission on wire rod and pipe and tube imports.

products markets would not get out of hand. On the other hand, if the majors had matched the lower price of imported rods, this would have lowered costs for the nonintegrated fabricators and served as a *carte blanche* invitation to cut product prices further than they had already been cut. In short, if the integrated steel companies were at all rational, we must presume that they concluded during the 1957-62 period that their losses from cuts in wire-rod prices, including the effect on products prices, would exceed the losses they suffered from relinquishing part of the noncaptive wire-rod market to imports. And this had to be a decision in which vertical considerations were paramount.

#### IV. *The Nonprice Response*

In a manner consistent with homogeneous oligopoly behavior, the domestic steel producers reacted to the import threat with a technological and political counterattack. The technological move was designed to introduce cost-reducing equipment and thus render the industry more competitive and less vulnerable to foreign steel produced under modern, technologically progressive conditions. The political stratagems were designed to insulate the domestic market from the incursions of foreign competitors—i.e., to restore the *status quo ante*, when the U.S. market was beyond the reach of less efficient, higher-cost foreign competitors.

#### *Technology*

The rising volume of steel imports—as well as the inroads made into steel markets by competing materials like aluminum, glass, cement, etc.—eventually persuaded domestic steelmakers to introduce modern production techniques already in widespread use in other major steel-producing countries. Most notable among these were the oxygen process and continuous casting. Both were adopted by major U.S. producers belatedly and with apparent reluctance.

The oxygen furnace, hailed as the greatest technical breakthrough since the shift from the Bessemer converter to the open hearth, requires only half the capital investment of the open-hearth furnace and yields operating savings of \$3 to \$10 per ton (depending on the facilities being replaced) [14, p. 14]. “Industry sources,” said the *Wall Street Journal*, “estimate that an oxygen unit can convert raw materials into steel for about \$8 to \$9 a ton. In an open hearth . . . the cost ranges from \$10 to \$15 a ton.” Equally impressive is its speed. According to Roger Blough, the oxygen process “is about eight times faster than the conventional open-hearth method” [26, p. 4]. Other estimates are more conservative: the oxygen furnace is said to produce twice as much steel as the open hearth and to shave \$3 to \$6 per ton off production costs [24, p. 1].

Despite these apparent advantages of the oxygen technique, and despite its widespread use in Europe more than ten years ago, the U.S. steel industry was slow to adopt it. McLouth, a minor producer, was the first to introduce an oxygen furnace in 1955, followed by Kaiser, another minor producer. The most oxygen capacity since then added in any one year was 3.3 million ingot tons in 1962. This year, another 10.2 million tons of capacity are scheduled to go into operation, and next year an additional 10 million tons are likely to be completed [25, p. 26]. The companies seem now to be persuaded that the oxygen process is here to stay and that it can provide sorely needed production economies.

The second major innovation recently adopted is continuous casting, which by-passes a series of steps currently needed in U.S. mills to shape liquid steel into semifinished solid metal. Without it, steel must first be molded and hardened into ingots; ingots must then be reheated in soaking pits, and the reheated ingots must then be sent through a rolling mill for squashing into slabs, billets, and blooms. Some of the equipment-makers claim remarkable cost savings for continuous casting—"a 30 to 50 per cent saving in capital costs and average operating savings of \$4 to \$6 a ton over today's standard techniques" [14, p. 14].

Continuous casting, according to *Iron Age*, "began moving in high gear abroad about eight years ago. Close to 40 machines were installed in the period from 1955 through 1962." The U.S. steel industry, however, did not take a second look at the new process until 1961. Except for a pilot plant at U.S. Steel's Chicago works, the first commercial continuous-casting unit went into operation in 1962—and, like the oxygen process, at the plant of a minor producer (Roanoke Electric Steel Corp.). With cost savings typically estimated at \$8 to \$10 per ton, it is not surprising that steel men forecast a \$1 billion investment in continuous-casting facilities over the next 10 to 20 years. "Within the next five years," says one, "every major mill and most minor ones will have at least one installation" [13].

In sum, both continuous casting and the oxygen process began to be introduced in U.S. steel mills at a significant rate only after the import threat became serious. They were adopted by major mills in the United States at least five years after European mills had recognized them as major cost-saving techniques. They were adopted after the U.S. industry had installed approximately 40 millions tons of new capacity that was obsolete almost the moment it was put into place.<sup>14</sup>

<sup>14</sup> [7, pp. 144-46]. Even though the integrated companies have begun to install oxygen and continuous-casting facilities, their wire-rod capacity still seems to lag behind the most modern European and Japanese plants. See, e.g., Kurt Orban, "A Discussion of Free World Wire Rod Mills Outside of the United States and Canada," *Wire and Wire Products*, Nov. 1962, 1603-12.

*Politics*

Faced with rising imports and possible erosion of its administered price structure, yet unwilling to meet foreign competition in the market place, the steel industry turned for relief to the government. Invoking the provisions of the Antidumping Act of 1921, eight major steel companies requested the Secretary of the Treasury to certify that West European and Japanese wire rods were being imported into the United States at less than fair value; they requested the Tariff Commission to find that a U.S. industry was being injured or likely to be injured by reason of the importation of such merchandise; finally, complainants asked for the assessment of antidumping duties in an amount equal to the difference between the import price and the foreign market value in the exporting country [23]. The obvious purpose of the complaint was to alleviate pressure on the domestic price structure and to build a *cordon sanitaire* around the domestic wire-rod market.<sup>15</sup>

The rationale of the complaint was the doctrine of fair competition. Dumping, according to the U.S. producers, was a simple matter of arithmetic; whenever a foreign producer charges a higher price in his home market than in the export market, he is guilty of unfair discrimination and unfair competition. He can practice dumping only because he enjoys a privileged position in his home market—through artificial restraints like tariffs, quotas, cartels, etc.—and this enables him to wage an unequal competitive battle against his dumping victims. (“The Dodgers,” as Roger Blough explains it [3, p. 4], “would experience difficulty maintaining a semblance of league leadership if the teams they compete against were allowed to take four strikes per batter against their three.”) Dumping, therefore, should be prohibited because it promotes unfair competition; because it is inherently discriminatory; because it interferes with the continuity and efficiency of domestic production; and because it does not provide domestic consumers with a dependable “low-cost” source of supply. Dumping, in short, undermines the integrity of *competition* and has a deleterious effect on domestic *competitors*.

In response to the complaint, the European exporters readily conceded that they were discriminating—that the price charged in the United States was lower than that in their home market. They pointed out, however, that their U.S. price was simply designed to meet the equally low price of their Japanese competitors. The Japanese, it was es-

<sup>15</sup> Nevertheless, M. A. Adelman states: “It must be said, to the credit of the steel executives, that they have refrained from cry-baby complaints about ‘unfair’ competition from foreign steel. This is a privilege reserved generally to small business industries.” “Reply,” *Quart. Jour. Econ.*, May 1962, p. 327.

tablished, were the price leaders on imported wire rod in the U.S. market and, ironically enough, they could not be convicted of dumping—even in an arithmetic sense—because their U.S. prices were identical to their home-market prices. Moreover, the exporters asked the Tariff Commission how the domestic steel industry could argue that the influx of 644,000 tons of foreign wire rod, valued at roughly \$65 million could cause it serious injury—when a Bethlehem executive said that the loss of his corporation's shipyards (accounting for 12-15 per cent of Bethlehem's billings, 10 per cent of its net, 6 per cent of its total investment, and \$152 million of its revenues) would "hardly cause a ripple in Bethlehem" [5, p. 248]. How could the domestic producers claim injury through unfair competition when the entire Belgian steel *industry* was hardly bigger than a single *plant* (Sparrows Point) of a single U.S. producer? Furthermore, how could the domestic industry claim injury from imported wire rods, when it failed to respond in any way to meet the threat of such imports through price reductions in the market place? Finally, the exporters asked, how can the domestic industry blame others for an injury which, if it exists at all, is self-inflicted—an injury which stems from the fact that wire rods happen to be the most extreme and dramatic example of the U.S. steel industry's noncompetitive, insensitive, administered price policy? Such injury, the exporters concluded, as the steel industry may have suffered, it has inflicted on itself by choosing *sua sponte* to price itself out of domestic and world markets.

On a more analytical plane, of course, the exporters could have shown that discrimination between the home and export markets is not undesirable per se; that domestic concerns frequently resort to both personal and geographical price discrimination; that a variant of basing-point pricing has always been a hallowed tradition in American steel circles; and that, under U.S. law, price discrimination is perfectly lawful where there is no substantial lessening of competition or tendency to monopoly, where differences in price can be accounted for by differences in cost, or where a discriminatorily low price represents the meeting of competition in good faith. Moreover, they could have argued that, in industries dominated by few sellers, discrimination is perhaps the only technique for eroding an oligopolistic and inflexible price structure—that in the absence of such discrimination there might be no competition at all. Indeed, they could have pointed out, as their U.S. counterparts had so often done before various antitrust agencies, that, in situations where sellers are few, the absence of discriminatory pricing is not an index of competition but collusion—evidence that some follow-the-leader, live-and-let-live scheme is in effective operation. To protect the domestic industry from "dumping" would have

meant its insulation from needed competitive pressures. It would have protected the industry from the bargaining power of its customers rather than affording its customers (the independent fabricators) protection against oligopolistic exploitation. This would have been tantamount to fostering the Robinson-Patman style of "soft" competition that the U.S. steel industry had always decried.

In any event, the Tariff Commission dismissed the dumping complaint on the ground that it could not find actual or probable injury to the domestic steel industry [21]. In so doing, the Commission, ironically enough, accepted some of the very arguments in the field of international competition that the industry had intended only for domestic consumption.

Defeated in its dumping action before the Tariff Commission, the industry began to press its case in two new forums. It pleaded with Congress to amend the antidumping legislation with a view to giving the domestic market more adequate protection against "unfair" foreign competition.<sup>16</sup> At the same time, steel spokesmen called for international industrial diplomacy to clean up what Roger Blough called the "international trade jungle" [3, p. 15].

European Coal & Steel Community (ECSC) producers have voiced similar demands. Complaining about the "market disruption" resulting from burgeoning imports, especially from the Soviet bloc, Japan, Great Britain, and Austria,<sup>17</sup> they have begun to call for ententes, accords, understandings, and accommodations—i.e., the reconstitution of what in impolite society would be called an international steel cartel.<sup>18</sup>

<sup>16</sup> In a spirit of bipartisanship, Senators Humphrey (Dem.-Minn.) and Scott (Rep.-Pa.) have introduced S.1318 to "improve the substance of the (Antidumping) Act through elimination of loopholes" and to "provide more effective procedures." In some quarters, however, their effort is perceived as part of a new drive for U.S. protectionism. See, e.g., *The American Swedish Monthly*, July 1963, Dec. 1963, and Feb. 1964, and *Norwegian American Commerce*, May-June 1963 and July-Aug. 1963. Also noteworthy in this connection are the current deliberations on "dumping" by the U.S. Treasury, the Tariff Commission, and the Trade Information Committee of the Office of the Special Representative for Trade Negotiations (the Herter Committee). *Wall Street Journal*, March 18, 1964, p. 30.

<sup>17</sup> "This increase in the volume of imports, linked to the world steel surplus," reports the ECSC High Authority, "is effected at marginal prices. The joint effect of the increase in imports and the low prices at which they are sold, is a constant and growing pressure on the prices charged on their own internal market by Community steel firms. The steel firms are obliged to offer important reductions, through the system of price alignments, in order to maintain their position in the market." Press Release, Washington, Jan. 16, 1964. See also *Wall Street Journal*, April 29, 1963, p. 5; Jan. 8, 1964, p. 5; Jan. 17, 1964, p. 5; Bureau of National Affairs, International Trade Reporter's Common Market Survey, Dec. 6, 1963.

<sup>18</sup> See, e.g., address by Dr. Hans-Guenther Sohl before the Biennial Meeting of the German Iron and Steel Industry Association, Duesseldorf, July 9, 1963; "Stahlkrise: Der Tonnenmacher," *Der Spiegel*, July 10, 1963, pp. 22-34, and the readers' comments thereon

### V. Conclusion

The foregoing analysis has dealt with the behavior of both the vertically integrated and the nonintegrated segments of the steel industry under the impact of substantial imports of raw materials and fabricated products. We have catalogued the diverse responses of the industry to these imports and described the resulting modifications in market behavior. If it has shown nothing else, our case study has demonstrated that vertical market power leaves its characteristic imprint on business policies.

Our findings, it should be noted, are at odds with recent literature on the subject. Spengler, for example, notes that if restraint of trade exists, "it is the horizontal elements that need to be singled out for remedial treatment" [15, p. 352]. Adelman claims that "Vertical integration has no economic importance except as an extension of a pre-existing horizontal situation: market share or market control" [2, p. 509] [1]. To Bork, vertical integration is "almost entirely lacking in significance as an analytical tool." He argues that monopoly power is the power to alter market price; that such power depends on percentage control of the market and ease of entry; that vertical integration does not change either the degree of market control or the ease of entry; that vertical integration does not affect price policy because an integrated firm will maximize profits at each level and set output as though each level at which it operates were independent from all other levels (except in the bilateral monopoly case); that the vertical squeeze, therefore, is an optical illusion—representing nothing more than price cutting at one level in the vertical chain [4, pp. 194-201].

The Spengler-Adelman-Bork position is not in accord with the facts of life in the steel industry. To be sure, the nonintegrated fabricators responded to lower import prices on the individual products they produced because failure to do so would have meant extinction. As producers of a single product—or, at most, a handful of products—they had no alternative than to meet the price reductions precipitated by imports. In addition, they responded to the compression of their fabricating margins by turning in ever-increasing numbers to imported wire rods—that is, to lower-priced supplies of their basic raw material. Their reaction in both the product and raw-material markets, therefore, was roughly in accord with the profit-maximizing calculus applied in a horizontal context.

The integrated firms, by contrast, in a calculated effort to protect the industry's price structure refused to meet the import prices either

---

in *Der Spiegel*, July 31, 1963, pp. 6-9, which blame the European, and especially the German, steel "crisis" on the Eurocrat planners in Brussels and the industry leaders who believed their overoptimistic prognostications on steel demand.

of products or rods. On some products, the integrated giants lowered prices to meet price cuts of their domestic nonintegrated competitors. Elsewhere, they preferred to abandon the field to imports altogether rather than to reduce their product prices. For the integrated firms, abandonment was a substitute for adjustment in response to exogenous market stimuli. Moreover, the integrated majors—unlike the horizontally oriented fabricators—never turned to imported rods in order to improve their competitive position. Given their vertical organization, they were quite understandably committed to an investment in their own supply channels [6, p. 432] [9, pp. 97-99] [11, pp. 120-23], and therefore resisted *in extremis* any resort to lower-cost supply alternatives. While the independents were successful—at least temporarily—in meeting the import challenge in products by using lower-priced foreign rods, their integrated rivals could not embrace this solution, which for them would have meant a denial of the *raison d'être* of vertical integration. To the integrated firms it obviously seemed preferable to abandon a single-product line than to jeopardize their investment in an entire branch of the industry.

At the wire-rod level, the integrated firms seemed to react perversely to the import threat. They first raised prices (1955-58) and then maintained them with catatonic insensitivity (1958-63.)<sup>19</sup> They did so, not

<sup>19</sup> According to the Spengler theory on vertical integration, rational monopolists or oligopolists would transfer semifinished products from one stage to another at prices free from monopolistic profits, thereby permitting the final price to be set at a lower figure than a price resulting from a series of transactions between independent bilateral oligopolists. If the steel industry conformed to Spengler's hypothesis, the transfer price for wire rods should have been affected by, if not identical with, the cost of imported rods of commensurate quality. The consequent reduction in the cost of wire-rod inputs to the wire divisions should have depressed the price of wire and, ultimately, wire-products prices.

That prices did not behave as the hypothesis suggests is obvious. It is instructive to inquire why. First, the structure of the industry was not that envisaged by Spengler. Integration is not complete, but is tapered forward, so that prices for wire rod and wire are not merely accounting transfer prices, but have a function vis-a-vis independent customers. Second, these prices are fixed by an administrative process, in the course of which a number of forces are brought to bear on price determination. Not only do the industry leaders take into account target return, but also the possible interactions of prices of wire rod, wire, and wire products, and the attitudes of customers to changes in accustomed differentials. Third, we may doubt whether, in any event, Spengler's optimism is warranted. There is little to show that transfer prices within a vertically integrated firm would, in actuality, be set at lower levels than market prices. In most U.S. industries, oligopolistic pricing policies, which might be expected to set prices in the market, would be regarded as proper procedures by managers responsible for transfer pricing within a vertically integrated firm. Hence, we would not anticipate that a shift to vertical integration in an industry already characterized by horizontal oligopoly would be reflected in appreciable price reductions because of elimination of interstitial profits. In fact, the probabilities would seem to lie in the opposite direction. While a horizontal oligopoly might be immediately affected by import competition, and forced to modify its pricing procedures and standards, a partially vertically integrated industry could continue to resist such pressures at one level, maintaining "cost" constituents that a horizontal oligopoly would have been forced to abandon.

only because of their addiction to cost-plus, target-rate-of-return pricing, but more importantly in an attempt to maintain the vertical relationship between wire-rod and wire-product prices. Indeed, their crucial counterstrategy was to stop the swelling tide of rod imports by political means, i.e., the antidumping proceeding, in order to cut off the vital supply of (cheap) raw materials to their independent customer-competitors and thereby to protect the vertical price structure from erosion. Their objective was not to safeguard their wire-rod price *per se* or their products prices *per se*, but to preserve their dominance and control over the entire vertical chain. And this they could only accomplish as long as they were in a position to parlay their horizontal market control in the rod stage into strategic leverage over the product stage.

If vertical integration were irrelevant to price behavior, i.e., if the steel industry were organized in the form of successive horizontal oligopolies, the import phenomenon would clearly have had a different impact. At each stage, i.e., wire rods and wire products, the horizontal oligopolies would have greeted substantial imports in the same manner as they would the appearance of a nonconformist price-cutter. The majors would have had to respond in some fashion to the price threat—by (1) meeting it frontally, in the form of price reductions; (2) indirect cost reduction through turning to cheaper supply alternatives; (3) the construction of more up-to-date efficient production facilities; or (4) absorption of the interloper into the oligopolistic fraternity. Unless response (4) was feasible, the appearance of imports at, e.g., the fabricated-products level would have elicited not only a price response on products, but would have affected the derived demand for rods and, even with horizontal oligopoly in rods, sent shock waves through the entire vertical structure of the industry—forcing a sympathetic reaction in wire, wire-rod, billet, ingot prices, etc. A substantial volume of rod imports would likewise have had an immediate (or, at least, delayed) price response from a horizontally oriented oligopoly.<sup>20</sup>

Certainly no horizontal oligopolist would have preferred abandonment to adjustment as a market strategy; no rational profit-maximizer would have insisted on using a captive raw-material supply—on pain of dismantling his fabrication facilities and forfeiting his market position. The horizontally oriented nonintegrated fabricators could not

<sup>20</sup> Horizontally oriented oligopolies appear to have a rather low tolerance level for nonconformists. When imports captured 10 per cent of the automobile market in 1959, the Big Three suddenly discovered that the American public liked compact cars. In cigarettes, the Big Four instituted drastic price cuts directed at the so-called 10-cent brands when the latter's market share rose to more than 20 per cent in 1932. Even in a regulated oligopoly like airlines, the majors could not afford to ignore the marginal competition of the nonscheduled carriers, and felt compelled to introduce coach service and cut rates.

have afforded such a grand gesture; and it is significant that they did not make it.

## DIVIDENDS AND STOCK PRICES

By IRWIN FRIEND AND MARSHALL PUCKETT\*

The recent literature has been characterized by considerable controversy and confusion over the relative importance of dividends and retained earnings in determining the price-earnings ratios of common stocks.<sup>1</sup> The disagreement over theoretical specifications of the expected relationship seems to us to have reached a point of rapidly diminishing returns, with much of the disagreement reflecting differences in interpretation of the questions being raised. However, there do seem to be very real difficulties in the reconciliation of available empirical findings with almost any sensible theory, and in the derivation of more definitive tests to choose among different specifications. This paper, after briefly reviewing the relevant theory and earlier findings, will discuss the limitations of these findings, describe various approaches to avoiding these limitations, and present new results that seem more in accord with theoretical preconceptions.

Relative prices of different issues of stock at a point of time are presumably determined by suitable discounting of expected future returns. These returns may take the form of dividend income or capital gains, both of which, assuming rational behavior, should be estimated on an after-tax basis with a higher average tax applicable to dividend income than to capital gains.<sup>2</sup> The discount factor relevant to these expectations of future return is a function of both the pure rate (or rates) of interest and the degree of risk associated with a particular issue—the evaluation of risk reflecting both the subjective probability distribution of expected return on total capital of the issuer and the degree of financial leverage in the issuer's capital structure.

\* The authors are, respectively, professor of economics and finance, University of Pennsylvania, and economist, Federal Reserve Bank of New York. The Bank has no responsibility for any views expressed here.

<sup>1</sup> See Modigliani and Miller [14], Durand's "Comment" [3], and Modigliani and Miller's "Reply" [15]; Gordon [6] [7]; Fisher [4]; Benishay [1]; Miller and Modigliani [13]; Lintner [10]; and Solomon [17].

<sup>2</sup> The magnitude of this tax differential is difficult to evaluate, but available evidence indicates it may be smaller than commonly supposed. For instance, past yield spreads between institutional grade corporates and tax-exempt bonds are explained by an investor tax bracket of approximately 20 per cent-25 per cent. However, in view of the institutional forces affecting the corporate bond market, this figure is undoubtedly lower than the tax rate characterizing the marginal investor in the stock market—but we have no idea just how much lower.

The fact that investors are willing to hold (or buy) a company's shares at the prevailing price implies that the rate of discount which equates their income expectation with market price constitutes a rate of return at least as high as could be obtained in alternative investments of comparable risk. Now, if these investors are willing to increase their holdings of shares at the same rate of market return, they should also be willing to forego current dividends insofar as the added equity investment yields this rate. Stated another way, investors should be indifferent if the present value of the additional future returns resulting from earnings retention equals the amount of dividends foregone. Moreover, because increases in present value (market price) are realizable as capital gains, earnings retention carries a tax advantage that lowers the rate of return on corporate investment necessary for shareholder indifference between current dividends and earnings retention.

The influence of earnings retention on share prices should therefore be a function of the profitability of corporate investment opportunities, *ceteris paribus*, in view of the fact that external equity financing is generally not a completely satisfactory substitute for internal financing. When this corporate rate of profit exceeds the minimum rate required by stockholders, price should increase as the proportion of earnings retained increases (though, since profitability is presumably a decreasing function of the amount of investment, beyond some point increased retention associated with excessive investment may depress the marginal return on investment below the required rate). Conversely, when the corporation's profit rate is less than the market rate, price should decrease with increasing earnings retention.<sup>3</sup>

Despite these theoretical conclusions, empirical findings indicate that, when stock prices are related to current dividends and retained earnings, higher dividend payout is usually associated with higher price-earnings ratios. This result, it might be noted, is found just about as often in highly profitable "growth" industries as it is in less profitable ones. Probably the earliest and best-known observation of this "dividend effect" was made a generation ago by Graham and Dodd [8], who went so far as to assert that a dollar of dividends has four times the average impact on price as does a dollar of retained earnings.<sup>4</sup> More recent statistical studies by Myron Gordon, David Dur-

<sup>3</sup> As Miller and Modigliani [13] have shown, external equity financing destroys this relationship under conditions of costless flotation and no capital gains tax advantage, if changes in dividends are compensated by changes in external equity financing of equal magnitude and opposite direction (rate of equity investment held constant). However, flotation is not costless, capital gains tax advantages do exist, and the rate of earnings retention is in all likelihood greatly influenced by the rate of investment.

<sup>4</sup> The fourth edition (1962) of this text on security analysis modifies this conclusion only moderately.

and, and others indicate that the dividend multiplier is still several times the retained earnings multiplier, with Gordon [6] finding little change on the average in the four-to-one ratio of the two multipliers, though the ratio varies widely and inconsistently from industry to industry and from year to year. These statistical results, it might be noted, are based on a large number of cross-section studies utilizing linear and logarithmic (and occasionally even other)<sup>6</sup> relationships between prices and both dividends and retained earnings to explain price variations in samples of companies drawn from particular industries.

Despite the massive array of statistical results tending to confirm the existence of a strong dividend effect, many market analysts have become increasingly skeptical of their validity. With the rise in market emphasis on growth in recent years, and the presumed close relationship between growth and retention of earnings in the minds of investors and managements, it seems strange to many analysts that a dollar of retained earnings (or of total earnings) should be valued so low relative to a dollar of dividends—and even stranger that there seems to have been no substantial shift in the relationship in recent years. Moreover, these doubts are supported quite strongly by several past surveys of shareholder opinion that indicate earnings and capital gains do, in fact, weigh more heavily than dividends in evaluating the relative desirability of alternative stock investments: "Investors who say a change in corporate earnings would influence their investment decisions outnumber by three to one those who would be influenced by a change in dividends."<sup>7</sup>

The behavioral assumptions necessary for theoretical support of a consistently lower market valuation of retained earnings than of dividends are also quite suspect. This lower valuation could exist if any one of the following situations is present: (1) the average holder of common stock possesses, at the *margin* of his portfolio, a very strong preference for current income over future income (a situation which hardly could be expected to persist over time); (2) the expected increase in earnings arising from increased per-share investment is viewed as involving a much higher degree of risk than that attaching to earnings on existing corporate assets; (3) the profitability of incremental corporate investment, as viewed by shareholders, is extremely low relative to the competitive yield prevailing in the stock market.

Each of the first two of these assumptions implies high rates of discount on incremental investment which would result in little short-run

<sup>6</sup> See, e.g., Johnson, Shapito, and O'Meara, Jr. [9].

<sup>7</sup> Friend and Parker [5]. Also see Merrill Lynch, Pierce, Fenner and Smith [12]: "Just about all surveys of shareholders in recent years show investors are primarily interested in one thing—capital gains—almost two-thirds of our customers placed this at the top of their list. . . . The emphasis on appreciation rises as income rises."

price appreciation from earnings retention, even though the expected profitability of additional investment may be quite high. However, neither of these assumptions is consistent with observed behavior of the market. Contrary to what might be expected from both of these assumptions, we do not normally witness perceptible drops in the market price level when the aggregate supply of corporate stock is increased by new issues, requiring for their absorption the substitution of current for future income and potentially raising the risk premium demanded by investors; nor do we typically witness sharp drops in per-share price when the supply of an individual company's shares is increased. It is possible to infer of course that these increases in supply are precisely timed so as to be automatically offset by upward shifts in investor expectations, but this seems completely unrealistic. Thus, both of these first two assumptions can be questioned on the basis of market behavior as well as logical content.

The third assumption—that investors view the profitability of incremental investment as being quite low—also seems highly suspect. Marginal profit rates in a substantial number of industries appear to be quite high, and undue pessimism is hardly consistent with the accepted image of the average shareholder. Moreover, the generally favorable market reaction to new public stock offerings in recent years further belies the prevalence of any pessimistic beliefs about marginal profit rates.

In view of all this, it is our opinion that those statistical studies purporting to show a strong market preference for dividends are in error—especially since the analysis typically employed (described in the following section) includes as a part of the market's valuation of retained earnings the price paid for the relatively high internal rates of return which might be expected to be associated with high retention. Nonetheless, we would still not expect to find a uniform preference for dividends even if internal rates of return were held constant over the sample of companies being examined.<sup>7</sup> We do not, however, deny the existence of instances in which retained earnings are valued less than dividends. Certainly, some companies may be controlled by managements who knowingly do not act in the shareholder's best interest, or there may be sharp disagreement between these two groups over how that interest is defined. However, we feel that these instances are likely to be the exception rather than the rule. Moreover, we would

<sup>7</sup> Lintner [10] maintains that under certain types of uncertainty retained earnings would be preferred to dividends if the alternative is a new stock issue to finance a given investment. If this is true, though we have some doubts, it would reinforce our argument. On the other hand, again as a result of uncertainty, Lintner argues that for firms with low leverage, investors will prefer higher dividends associated with higher corporate debt to greater retention and lower dividends.

expect that for the average firm, irrespective of investor preferences between dividends and capital gains, payout policies are such that at the margin a dollar of retained earnings should be approximately equal in market value to the dollar of dividends foregone.

### I. *Possible Sources of Statistical Bias*

In support of our position, we will now outline a considerable number of reasons why previous statistical studies yielded biased results. These comments are directed in particular at the following regression equation, which is the one most commonly applied to cross-section data, but most of them also apply to past variations in this equation:

$$(1) \quad P_{it} = a + b D_{it} + c R_{it} + e_{it}.$$

Reading from left to right, the variables represent per-share price, dividends, and retained earnings. The subscript  $i$  denotes the  $i^{\text{th}}$  company in a sample of  $n$  companies selected from a particular industry, and all variables are measured in the  $t^{\text{th}}$  time period.

Before discussing the reasons for bias in the application of this relation, we might point out that even those who believe that a higher  $b$  than  $c$ —the typical result—indicates investor preference for dividends seem nonetheless to feel that the optimum earnings payout ratio is normally less than one, which could be regarded as inconsistent with the result obtained. The implicit assumption in the above equation that optimal earnings payout—i.e., that giving rise to the highest price-earnings ratio—is either all, none, or a matter of indifference is, of course, highly questionable. However, even though this equation is quite deficient in that it does not admit of a unique optimum payout between the extremes of zero and 100 per cent, it may still be quite useful for estimating price behavior within the observed range of dividend payout.

Thus, if the companies in a sample tend, *on the average*, to pay out less than the optimum,  $b$  should be greater than  $c$ ; if they pay out more than the optimum,  $b$  should be less than  $c$ ; and if they pay just the optimum, regardless of what that optimum is, or if the payout is a matter of indifference,  $b$  should equal  $c$ . Theory would suggest that regardless of the optimum payout for any individual company, at that optimum \$1 of dividends would on the average have the same effect on stock price as \$1 of retained earnings.<sup>8</sup> Any difference between the values of  $b$  and  $c$  therefore represents either a disequilibrium payout position or a statistical limitation of the analysis employed, including most notably a correlation of dividends or retained earnings with omitted

<sup>8</sup> This conclusion does not depend on whether, under uncertainty, the relevant discount rate of investors is a function of the dividend rate.

factors affecting price. Our analysis will attempt to distinguish between these two possibilities, though the persistence of the relative importance of payout on price, and its apparent invariance to such factors as the rise in market emphasis on growth through earnings retention, argues against the disequilibrium explanation even if this condition is regarded as fairly permanent.

While the linear form used does not provide measures of optimum payout, it can give useful insights into the size of such payout through examination of the residuals over the range of payout experienced. However, an adequate study of the size of optimal payout ratios under varying circumstances requires a more complex statistical analysis, allowing for many more variables than have been incorporated in the framework used in this paper, and will be deferred to a subsequent study. Our analysis in this paper is directed only to an assessment of the general rationality of company payout policy in view of the usual findings (i.e.,  $b$  systematically higher than  $c$ ) which imply that management typically tends to maintain too low a payout.

It will be noted that the following discussion of regression problems centers exclusively on those encountered in cross-section analysis. While it is possible to work with time-series information, and we shall do so to a limited extent, virtually all of our predecessors used cross-section data in their regression studies, and it is these studies with which we take issue.

#### *A. Omitted Variables*

The above equation assumes, among other things: (1) either that risk is held constant by restricting the sample to a particular industry or else that dividend payout is uncorrelated with risk; and (2) that expectations of growth are determined solely by the relative amount of current earnings retention or alternatively that growth from other sources is uncorrelated with the relative amount of retention.

With regard to the first of these assumptions, a typical sample of 20 or so companies drawn from industries such as foods, steels, or chemicals contains enormous variations in company size, financial structure, and product mix; therefore, it appears totally unwarranted to assume that risk variations within these industry samples are negligible. In view of what we know about managerial desire to avoid dividend cuts, it certainly seems logical to expect that companies facing greater uncertainty about future profit performance would adopt lower current dividend payout as a means of hedging the risk of being forced to cut their dividend. Thus, high risk may *result* in both low payout and low price-earnings ratios, whereas low risk may *result* in high payout and high price-earnings ratios. Consequently, omission of a risk variable

from the regression equation could conceivably impart a substantial upward bias to the dividend coefficient, depending upon both the extent to which risk varies between companies and the strength of risk in determining current payout.

It might be noted that a few previous writers have incorporated a risk variable in the regression equations. However, this variable is usually measured in terms of earnings fluctuations, and is heavily influenced by cyclical factors in the company's operating performance. We are inclined to doubt that cyclical earnings variability is a good proxy measure of investor uncertainty about future long-run performance, and therefore are dubious that the problem of risk has been handled properly.

Now, the second assumption—that growth deriving from sources other than earnings retention is either nonexistent or nonbiasing—is equally questionable. Growth in per-share earnings, apart from that arising from more efficient use of existing capital, can occur through externally as well as internally financed investment, and there may be a biasing correlation within a sample of companies between internally and externally financed growth. Suppose, for instance, that some companies prefer (or in the case of public utilities are encouraged by regulatory agencies to have) low earnings retention compensated by large amounts of external financing, whereas other companies prefer high earnings retention and small amounts of external financing. This would impair the relationship between earnings retention and growth, thereby reducing the coefficient on retained earnings when the variable measuring externally financed growth is omitted.\*

However, it is equally possible that the relationship between internal and external financing could run the other way—that is, that high rates of retention are associated with relatively heavy external financing and low rates of retention with small amounts of external financing. The inherent advantages of retained earnings undoubtedly encourage maximum use of this source of funds before resorting to the capital markets. Thus, external financing may be associated with high earnings retention for companies with abundant investment opportunities, whereas the absence of external financing may be associated with lower earnings retention for other companies. In this case the rate of earnings retention is positively correlated with external financing, and

\* If the objective were to arrive at the relative evaluation of dividends and retained earnings *with a given internal rate of return*, then the problem of bias would arise from the omission of the expected growth rate rather than from that of externally financed growth. An analysis which includes past growth rates (as proxies for expected future growth) is Benishay [1]. Gordon [7] does introduce both internally and externally financed growth, but the form of the relation he uses does not permit the isolation of dividends from retained earnings effects.

the retained earnings coefficient is biased upward by omission of any consideration of externally financed growth.

In summary, whereas the bias due to omission of a risk variable is reasonably clear in direction (but not in magnitude), the nature of the bias resulting from omission of a variable to take account of externally financed growth is not clear. Nonetheless, both of these variables are potentially too important to be omitted from the regression equation without proof of the negligibility of their influence on regression results.

### *B. Regression Weights*

Contributing to the difficulties imposed by omitted variables is the separate but correlated problem of regression weighting. An individual observation influences regression results according to the extent to which that observation departs from the sample average. Thus, extreme values are much more important in determining regression results than are those values centered more closely about the sample average.

Now, it is a generally accepted fact that high-quality stocks tend to be characterized by high per-share values (prices, dividends, and earnings), whereas low-quality stocks are characterized by low per-share values. Further, as discussed immediately above, high-quality stocks may tend to pay out a higher proportion of earnings than do the low-quality issues. Thus, the association between regression weights and investment quality may exaggerate whatever regression bias exists due to an association between investment quality and dividend payout. This problem of regression weights is reduced when regression variables are converted to logarithms, which was done in some earlier studies.

### *C. Random Variations in Income*
